From some of our flow tests we feel that the authors have somewhat underrated the high nickel-high chromium austenitic steels. Our tests of these steels at temperatures of 900 deg. and over have shown that they resist considerably higher stresses than the non-austenitic alloys. Two such alloys which we have tested are 23 per cent nickel–7 per cent chromium and 23 per cent nickel–17 per cent chromium. These austenitic steels, while having very good physical properties, are difficult to fabricate, a serious factor and an additional problem for the manufacturer, the cost of which

[12] Crane Company, Chicago, Ill.

eventually, of course, is passed on to the customer in one way or the other.

The authors of the paper remark on the effect of grain size. In our A.S.T.M. paper of June, 1928, on "Long Time or Flow Tests of Carbon Steels at Various Temperatures, With Particular Reference to Stresses Below the Porportional Limit," we called attention to the fact that our tests showed that steels of larger grain size resisted flow at higher stresses than the same steels in which smaller grain size was produced by heat treatment or other method such as forging. We already had evidence from our flow tests that well-known alloy steels behaved similarly. This of course brings up the question whether forgings or castings or other products for high-temperature service where highest resistance to flow is desired should have the fine grain which the engineer for many years has considered so desirable. He long has considered ductility, as measured by high elongation before breaking, the end to be sought for. The old standard of ductility probably was something like 25 per cent elongation in 2 inches, and if that was discounted and a stronger steel given by the manufacturer, he objected, preferring the lower strength with high ductility. As a case in point, something over ten years ago the alloy-steel stud was brought out for high-temperature bolting, and such alloy-steel studs have been used on 600 lb. and higher steam pressures at 700 deg. without failure. These studs were the basis of A.S.T.M. Specification A-96-28 for alloy-steel bolting for high-temperature service, of which Class C requirements are 105,000 lb. p.s.i. minimum yield point, tested at normal temperatures.

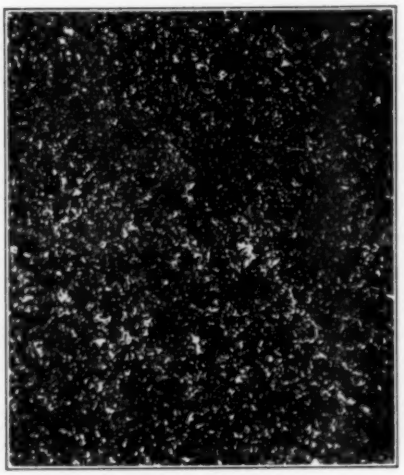
Naturally, such steel gives less than 25 per cent elongation in 2 inches, and the specification, based on actual experience was drawn calling for a minimum of 16 per cent. This Class C steel is being used very largely today, and apparently engineers now agree that it is better to have a high yield point with somewhat lower ductility than to have the less strong steel of low yield point with higher ductility. In other words, it seems to have come to this: So long as one gets reasonable ductility to avoid likelihood of extreme stiffness in the steel, it seems better to have a high enough yield point to cover operating stresses adequately so that flow or creep will be held to a minimum. With high enough yield point that the steel does not stretch under stresses and temperatures used, of what value is potential higher elongation which will never need be used? An elongation of 16 per cent is the minimum limit given in the specification. Probably no one would care to advocate lower than 12 per cent, as we would get rather more rigidity and perhaps increase the danger of failure by shock. However, the 16 per cent minimum elongation with 105,000 lb. p.s.i. yield point does seem to be well justified, and now has the sanction of approximately ten years' satisfactory use.

It was formerly thought that ductility has something to do with the endurance value. Recent and very thorough tests have shown that the endurance value is not connected either with the ductility or with the yield point, but is higher as the ultimate strength is higher. These high-strength steel studs therefore should have increased endurance limit under vibration, which is one of the things desired in many installations.

Authors' Closure

Professor White. I quite agree with what Mr. Spring said, to the effect that there is a place for the high chrome-high nickel alloys. Those alloys without doubt will be found to have quite acceptable properties from the standpoint of resisting oxidation at these high temperatures, particularly corrosion where there is a possibility of wet steam from time to time.

The paper itself of course was dealing primarily with the stability of these metals at elevated temperatures and was confining most of its attention to a discussion of the alloys which will give the highest physical properties. It was from that standpoint, therefore, that the authors felt there were other alloys than these austenitic ones which had high properties.



We are glad to have Mr. Spring say what he did with regard to large grain size, although we feel that a small grain size is preferable with conditions below the equicohesive temperatures. When we are above we are inclined to believe in improvements brought about by a large grain size, and we are glad to get the confirmation with respect to that matter.

FSP-51-36

Influence of Coal Type on Radiation in Boiler Furnaces

By W. J. WOHLENBERG[1] and R. L. ANTHONY,[2] NEW HAVEN, CONN.

This paper includes the results of an application of the methods and data presented in a previous A.S.M.E. paper ("The Influence of Radiation in Coal-Fired Furnaces on Boiler-Surface Requirements, and a Simplified Method for Its Calculation," by W. J. Wohlenberg and E. L. Lindseth) to pulverized coal for a number of coals of widely varying composition. After an evaluation of radiation quantities for each of these coals, further investigation was made for the purpose of ascertaining what quantitatively measurable property of coals might be most significant in differentiating one from another during combustion with respect to the quantity of energy which is transferred as heat to the walls of a boiler furnace. It was found, of the properties investigated, that the calorific value serves as the most consistent and useful indicator of the radiation powers of a coal as burned in the pulverized form in boiler furnaces.

THE information contained in this paper is derived from the results of a large amount of painstaking calculation carried out by the men composing the graduate class in power engineering at Yale during the school year 1927–1928. At the outset, therefore, the authors wish to express their indebtedness to this group.[3]

The paper includes the results of an application of the methods and data presented by Wohlenberg and Lindseth[4] for pulverized coal to a number of coals of widely varying composition. After an evaluation of radiation quantities for each of these coals, further investigation was made for the purpose of ascertaining what quantitatively measurable property of coals might be most significant in differentiating one from another during combustion with respect to the quantity of energy which is transferred as heat to the walls of a boiler furnace. As will be shown later, it was found, of the properties investigated, that that one known as the calorific value serves as the most consistent and useful indicator of the radiation powers of a coal as burned in the pulverized form in boiler furnaces.

Haslam and Hottel include in their paper[5] a somewhat modified form of certain of the equations worked out by Wohlenberg and Morrow[6] on which the development of Wohlenberg and Lindseth is based. These modified formulas of Haslam and Hottel have a better mathematical basis than do those which they replaced in the Wohlenberg and Morrow analysis of this subject. Thus in the limits for exceedingly fine coal, the Haslam and Hottel formulas yield radiation magnitudes more nearly in accord with the facts than would be the case should the Wohlenberg-Morrow formulas be applied without correction to the same conditions. However, the inadequacy of the latter formulas for such conditions was recognized by the authors, so that the method of correction adopted resulted in radiation curves closely approaching the Haslam-Hottel curves.

Application of the two sets of equations to a particular set or sets of conditions leads to two sets of results which differ only slightly in magnitude. For instance, the computed radiation mean values of the flame temperature differ by only about 30 deg. for assumed conditions within the usual operating range.

In view of such small differences as these it appears that no material advantage could have been realized in this investigation by adopting the Haslam-Hottel system of nomenclature and constants. On the other hand, it will undoubtedly be advantageous to any who are familiar with the earlier papers[7] leading up to this subject to have the whole in harmony; i.e., to have a consistency throughout so that the relativity of things is not disturbed by a change in value of constants which in themselves lead to corrections so small as to be within the unavoidable error of necessary assumptions.

TABLE 1 PERCENTAGE ANALYSES OF COALS

	North Dakota lignite (4)	Washington sub-bituminous coal (5)	Colorado sub-bituminous coal (6)	Illinois bituminous coal (7)	Virginia semi-bituminous coal (8)	Kansas bituminous coal (9)	Pennsylvania bituminous coal (10)	Alabama bituminous coal (11)

Calorific value, B.t.u. per lb.	6,331	7,547	9,517	10,856	12,739	13,082	13,217	14,141

Individual Coal Types

Analyses of the coals investigated are shown in Table 1. The coals are numbered beginning with 4, because coals included in the Wohlenberg and Lindseth paper were designated by numbers 1, 2, and 3. It is to be noted that the eight coals included vary in composition from that of lignite to semi-bituminous coal, and the calorific value ranges from 6,300 to more than 14,000 B.t.u. per lb.

For each of these coals there are included flame and refractory isotherms similar to those given by Wohlenberg and Brooks,[8] and

FIGS. 1 TO 8 FURNACE-FLAME ISOTHERMS FOR VARIOUS COALS
(20 per cent excess air.)

FIGS. 9 TO 16 FURNACE-REFRACTORY ISOTHERMS FOR VARIOUS COALS
(20 per cent excess air.)

also heat-transfer curves showing the rate of heat transfer per square foot of projected cold, bare furnace-wall surface. It is to be noted that in all cases the air excess has been taken at 20 per cent and the furnace cavity as a cube 20 × 20 × 20 ft. containing a flame 19 × 19 × 19 ft. This is furnace No. 2 of Wohlenberg and Lindseth. The initial mean particle diameter entering the burner is taken as equal to 0.002 in. for all coals, which according to the analysis by Wohlenberg and Morrow is about that for 75 per cent through a 200-mesh screen. It should be noted in particular that the energy-release figures are all based on the volume of the flame and not that of the furnace. The total energy released is thus energy-release rate × 6859 (the assumed flame volume), and not energy release × 8000 (the furnace volume).

Results are shown for furnaces of several radiation symmetries. In all cases Furnace A, as in the former papers,[9] denotes a cube, the top face of which is covered with bare-iron water-cooled surface. Furnace B has both the top and bottom faces occupied by bare water-cooled surfaces, and Furnace E has all faces occupied by bare water-cooled surfaces. Walls not covered by bare water-cooled surfaces present uncooled refractory faces. The term "fraction cold ψ" denotes the fractional part of the furnace envelope which is occupied by bare-iron water-cooled surface. Thus for Furnace A the fraction cold ψ is equal to one-sixth, for Furnace B to one-third, and for Furnace E to unity.

As here described, the furnace envelope is comprised of bare water-cooled iron faces and more or less solid refractory faces. Water-cooled refractory faces should of course also be considered in a more complete analysis of the problem. An analysis including such furnace walls is under way. For the present, however, let it suffice to say that whatever influences are due to bare-iron water-cooled surfaces would also be present, but to a somewhat less degree for a refractory-covered water-cooled wall, other conditions being the same in both cases.

Flame and Refractory Isotherms

Flame and refractory isotherms for the several coals are given in Figs. 1 to 16, inclusive. Figs. 1 to 8, inclusive, have the radiation mean of the flame temperature as a constant on each curve, and in Figs. 9 to 16 the radiation mean of the refractory temperatures is a constant on each curve.

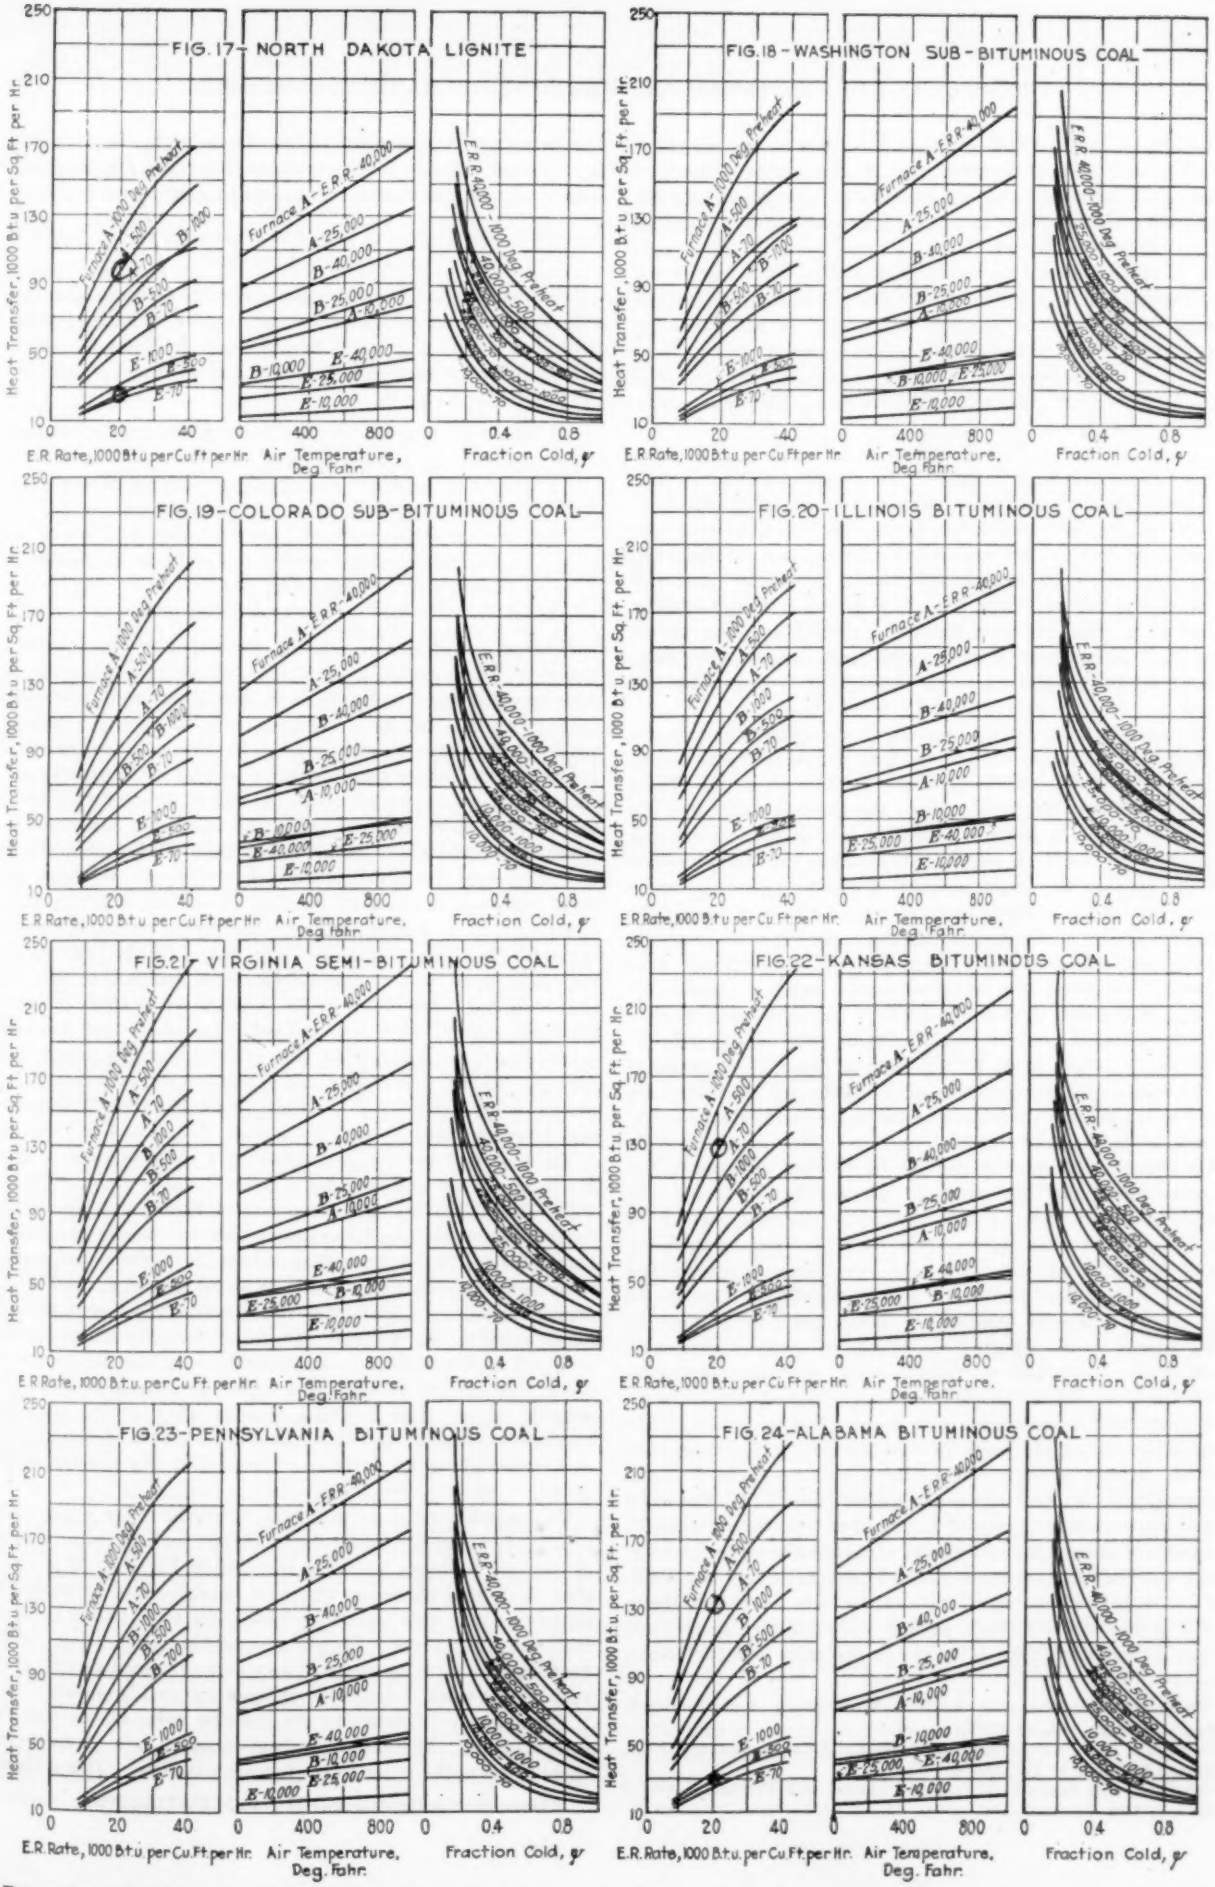
It is to be noted that the same kinds of curves have the same general shape regardless of fuel type, but that they are shifted up or down with respect to the axes, depending on fuel type. As an example, at 500 deg. fahr. air temperature Alabama bituminous coal, Fig. 8 (B.t.u. per lb. = 14,141), requires an energy-release rate of very nearly 20,000 for fraction cold $\psi = 0.4$ when the mean flame temperature is 2400 deg. fahr. Under the same conditions the North Dakota lignite, Fig. 1, requires an energy-release rate of 33,000. If the fraction cold is unity and other conditions are as above, the required rate of energy release is 28,500 for the Alabama coal and 52,000 for the North Dakota lignite. Obviously the combustion of the *lower-grade* coals is accompanied by a higher rate of energy release for the same mean flame temperature, and vice versa, for a given rate of energy release the lower-grade coals are accompanied by a lower flame temperature, all other conditions being the same.

Such conditions should be reflected in the mean refractory temperatures. Thus, referring to Fig. 16, it is found that for the Alabama coal at a 20,000-B.t.u. energy-release rate with $\psi = 0.4$ and an air temperature of 500 deg. fahr., the mean refractory temperature is about 1930 deg. fahr. For the North Dakota lignite, Fig. 9, at a 33,000-B.t.u. energy-release rate, corresponding to a 2400-deg. fahr. flame temperature, the mean refractory temperature is just above 1900 deg. fahr. For a 20,000-B.t.u. energy-release rate with the North Dakota lignite and $\psi = 0.4$ with the air temperature at 500 deg. fahr., the mean refractory temperature is about 1520 deg., as compared with 1930 deg. for the Alabama coal.

Neglecting the influence of impurities in the ash, it thus appears that the lower-grade coals may in general be burned at higher energy release than may the higher-B.t.u. coals. This is fortunate when it is considered that often the low-grade coals contain ash which is composed of low-fusing constituents and which may also otherwise attack the refractory.

Obviously the data included in these curves may be of some use in setting out by itself, as shown above, the expected influence of the radiation factors of the coal on the possible permissible rate at which the combustion process may be maintained. In all cases, however, it is essential that other factors such as slagging, erosion, proper conditions for good combustion, etc., be given thorough consideration. In this study these factors have been ignored, which simply means that they have been assumed as constant for all coals, and this assumption is made for the sake of isolating the radiation factor so that its variation in magnitude with different coals may be ascertained.

Heat Transfer at the Water-Cooled Surface



Figs. 17 to 24, inclusive, contain curves plotted in three different ways to show the variation in rate of heat transfer at the water-cooled furnace wall. The ordinates in all figures represent the rate of heat transfer per square foot of bare water-cooled surface as projected into the plane of the furnace wall at which it is located. The abscissas, taken from left to right, represent rate of energy release, air temperature, and fraction cold.

The groups of curves on the left-hand side of each figure show a steep rise in rate of heat transfer with rate of energy release for any given furnace, air temperature, etc. The groups of curves in the center show that the rates of heat transfer vary practically in a straight-line ratio with increase in air temperature, and the right-hand group shows how the heat-transfer rate per square foot of surface decreases as more bare cold surface is placed in the furnace, other conditions remaining the same.

To illustrate the influence of coal type, let us again consider the Alabama coal and North Dakota lignite shown respectively in Figs. 21 and 17. Taking first Furnace A ($\psi = 0.167$) with a 20,000-B.t.u. energy-release rate and 500 deg. air temperature, we find that for the Alabama coal the heat-transfer rate as above defined is equal to 132,000. For the North Dakota lignite, under the same conditions otherwise, the heat-transfer rate is 97,000. Thus for the lower-grade coals the heat-transfer rate is, as seen, considerably lower, and this persists regardless of furnace symmetry if for both coals the same furnaces, etc. are considered. Thus for the above conditions but for Furnace E ($\psi = 1.00$), the heat-transfer rate with the Alabama coal is 29,000 as against 25,000 for the North Dakota lignite.

It is to be noted that the above differences in rates of heat transfer to the water-cooled walls exist in spite of the fact that the total rate of energy liberation is the same in both cases for the same excess-air figure and for the same air temperature. Examination of the analyses of the two coals shows that for the North Dakota lignite the ratio of fixed carbon to volatile matter is 28.7 to 25, and for the Alabama coal, 59.6 to 31. The moisture contents are respectively 42.3 and 3.2 per cent. This high moisture content is partially responsible for a considerably higher thermal capacity in products of combustion per 10,000 B.t.u. of heat value of the North Dakota lignite as compared with that of the products of combustion of the Alabama coal on the same basis. Consequently a larger fraction of the liberated energy is absorbed by the products of combustion of the North Dakota lignite, which in itself leaves a smaller fraction to be transferred

[9] Wohlenberg and Morrow, Wohlenberg and Lindseth.

FIGS. 17 TO 24 HEAT TRANSFER AT COLD SURFACE IN FURNACE, B.T.U. PER SQ. FT. OF PROJECTED COLD SURFACE PER HOUR
(Plotted respectively against energy-release rate, temperature of air supply, and fraction cold. Excess air, 20 per cent.)

to the furnace walls. This accounts for a part of the difference in the two rates of heat transfer. Another part of the difference is accounted for by the above differences in ratio of fixed carbon to volatile matter. Since this ratio is greater for the Alabama coal, it follows that by weight the solids, or coked carbon particles, in suspension within the furnace cavity, will be larger for the Alabama coal than for the North Dakota lignite, resulting in a larger extent of carbon radiating surfaces for the Alabama coal. Thus from this source more heat is transferred to the walls in the case of the Alabama coal than is so transferred from the North Dakota lignite, and the total difference in the two cases is, as shown, of a considerable magnitude.

In computing the radiating surface of the solids in suspension the coefficient of volume change[10] during volatile distillation has been based on the same mean coke density for all of the coals and the validity of the above argument is based, to some extent at least, on the correctness of this assumption. Should the lignite particle swell considerably more in coking than the Alabama-coal particle, then, relatively speaking, more radiating surface from solid particles might be available in the lignite flame than it has been credited with, and consequently more heat would be transferred to the walls than is shown by the curves.

The rate of swelling of the particle in the ignition zone is dependent on the volatile content per unit weight of fixed carbon, the extent to which sticky or tarlike substances are formed as the volatile passes from the coal to the gaseous state, and the rate of heating. It appears that the rate of heating for the lignite particle must be lower than it is for the Alabama-coal particle, because the larger amount of moisture for the former will hold down the particle temperature as it is introduced into a furnace cavity in which, in turn, the radiation to the particle is itself less because of lower flame and wall temperatures, and probably because of less radiation from a smaller quantity of solids in suspension than would be so if the same furnace were fired by Alabama coal to yield the same total energy release. Consequently there must be considerably more time available for the volatile constituents to be dispelled through the interstices of the lignite particle than there would be for the discharge of the volatile from the Alabama-coal particle. This increased time factor probably operates to reduce the internal pressure in the particle during the gas-discharge period, thus reducing the tendency toward blowing up. Obviously the final answer to this question in quantitative form may be obtained only by actual experimental work of a most involved and painstaking nature. In a paper[11] before the International Coal Conference held at the Carnegie Institute of Technology, Pittsburgh, in 1926, Alfred White reported the results of some experimental work on the instantaneous carbonization of crushed and pulverized coal in which fine particles were dropped through a retort containing a reducing atmosphere. The tendency to abnormal swelling of the particles was observed under these conditions. It was noted, however, that the "cenospheres," as the abnormally swelled particles are called by Newall and Sinnatt,[12] had an outer shell composed of more or less transparent window-like patches of clarain tied together with ridges of carbon or coke. These window-like patches no doubt have a relatively low coefficient of radiation, so that in spite of the large increase in diameter it is doubtful if a single particle will emit very much more energy by radiation than it would in the more compact state. Furthermore the proportion of the clarain matter is very small in any coal, whence it appears that the foregoing method of evaluating the radiation from solids is reasonably correct.

Relation Between the Calorific Value of a Coal and Its Radiating Powers

In attempting to find a determining factor which, within reasonable limits of error, relates a coal to its radiating powers, George Vye, in a thesis,[13] investigated the influence of the following conditions on the radiating powers of a coal as fired in the pulverized form:

1 The total moisture content in the products of combustion yielded by a pound of coal
2 The total moisture content in the products of combustion yielded per 10,000 B.t.u. of heating value
3 The thermal capacity between 70 deg. and some high temperature of the products of combustion yielded per 10,000 B.t.u. of heating value
4 The calorific value of the coal, B.t.u. per lb.

Without going into a detailed discussion of the results at this time, let it suffice to state that, of the above factors, the calorific value was found to be most satisfactory as the determining factor. In Fig. 25 it is shown how the actual computed values of the flame temperatures fall for the conditions specified. It is seen that curves may be drawn so that with one exception the plotted values for all coals fall either on or very close to the curves. With this exception the maximum difference between curve and point values is less than 40 deg., but for the exception (coal No. 8, points shown in circles) the difference is in some instances as much as 100 deg. Coal No. 8 is very much like Coal No. 1, points for which are shown as crosses on the curve for the Type E furnace. The values for the latter points are taken from Wohlenberg and Lindseth, and it is to be noted that they fall much closer to the curve than do those in circles for Coal No. 8. It appears, then, that there may be some doubt about the accuracy of the computed temperature results for Coal No. 8. It is to be noted also that values for Coal No. 2, shown by crosses for type E furnace and taken from Wohlenberg and Lindseth, fall very near the curve.

The curves show that a coal having a calorific value of 9000 B.t.u. as against one that has a calorific value of 14,000 B.t.u. will result, for an energy-release rate of 10,000, in a flame temperature about 100 deg. lower for the same conditions otherwise in both cases. If the energy-release rate is 25,000 the corresponding reduction in flame temperature is about 150 deg., and if the energy-release rate is 40,000 the corresponding reduction in flame temperature is nearly 200 deg. Furnace symmetry has relatively a small effect on the magnitude of the differential in flame temperature caused by a variation in magnitude of the calorific value. This becomes obvious when noting that the curves for the A, B, and E furnaces are nearly equidistant from each other along the ordinates throughout the abscissa range shown.

The relation between rate of heat transfer per square foot of projected bare-iron water-cooled surface and the calorific value of the coal is shown for given furnaces in Fig. 26. It is noted that the points plotted to represent the calculated values fall so that in no case does the point value differ more than 6 per cent from the curve value. Thus it appears that within these limits, heat-transfer rates for any coal may be ascertained directly from such curves when the calorific value of the coal is known.

For a given difference in the calorific value of the coal the corresponding differential in heat-transfer rate increases as there is less cold surface in the furnace envelope. This is shown

[13] Presented for the degree of M.S. in M.E., Yale, 1928.

by the greater slope of the curves for types A and B furnaces when compared with the curve for the type E furnace. It is noted that this differential in heat-transfer rate increases also for increasing energy-release rates. Thus for an energy-release rate of 25,000 a shift from 9000 to 14,000 in the calorific value changes the heat-transfer rate from 28,000 to 30,000 for the type E furnace, whereas for the type A furnace the rates increase from 69,000 to 81,000 B.t.u. per sq. ft. per hour. If the energy-release rate is increased to 40,000 the heat-transfer rates increase respectively from 44,000 to 48,000 and from 161,000 to 193,000

ISOTHERMAL AND ISO-TRANSFER CURVES

Curves in Figs. 27, 28, and 29 show the relation between the calorific value of a coal and the required energy-release rate for a given mean flame temperature. The curves are flame isotherms for given furnace conditions when the coal is a variable. Similarly, the curves in Figs. 30, 31, and 32 are "iso-transfer" curves for given furnace conditions with the coal as a variable.

It is seen that the flame isotherms have more curvature toward the right at the lower ends than the iso-transfer curves have. On first thought it might appear that the iso-transfer curves should follow very closely the trend in curvature of the above flame isotherms. The relatively sharp curvature of the flame isotherms at the lower ends is largely accounted for by the increase in thermal capacity, per 10,000 B.t.u. of heat liberated from the coal, for coals of lower and lower calorific values. Thus for a given flame temperature a larger fraction of the liberated energy is retained in the gases when low-heating-value coals are

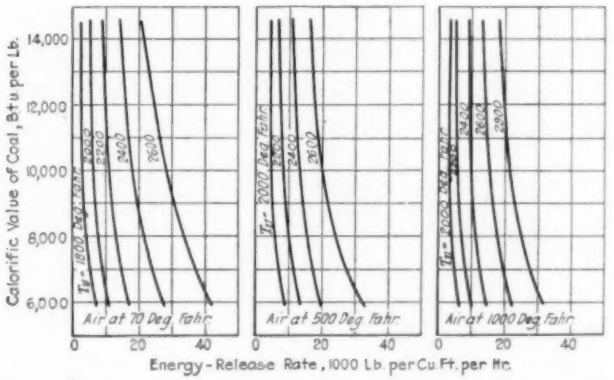

FIG. 27 INFLUENCE OF CALORIFIC VALUE OF COAL ON PERMISSIBLE ENERGY-RELEASE RATE FOR A GIVEN FLAME TEMPERATURE

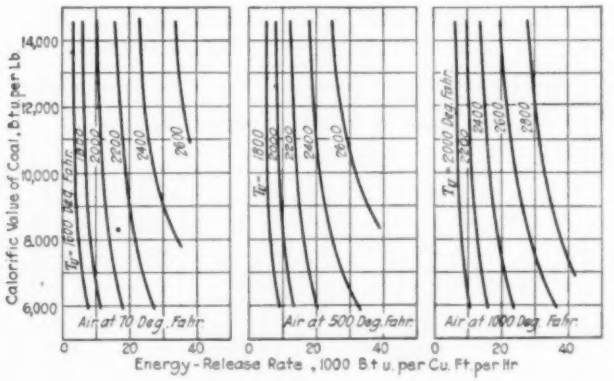

FIG. 28 INFLUENCE OF CALORIFIC VALUE OF COAL ON PERMISSIBLE ENERGY-RELEASE RATE FOR A GIVEN FLAME TEMPERATURE
(Furnace B, 20 per cent excess air.)

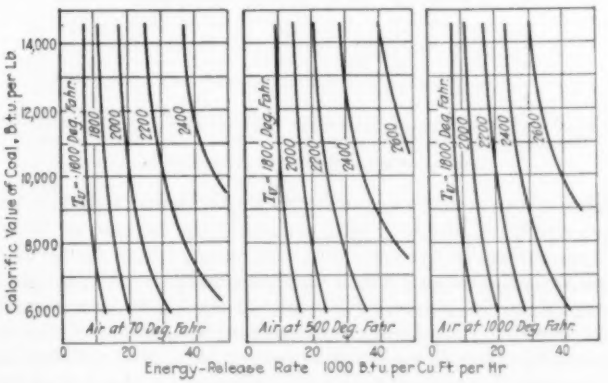

FIG. 29 INFLUENCE OF CALORIFIC VALUE OF COAL ON PERMISSILBE ENERGY-RELEASE RATE FOR A GIVEN FLAME TEMPERATURE
(Furnace E, 20 per cent excess air.)

burned than when high-heating-value coals are burned. It follows that for the lower-grade coals a larger amount of energy must be released to maintain a given furnace temperature.

At a given flame temperature, any increase in the radiation discharge from the flame of the lower-grade as compared with

that of the higher-grade coals will also be a factor in determining the trend of the curves toward the right. The trend of the flame isotherms is thus in general the result of two factors. The relative magnitude of these may be shown by an example. Referring to the left-hand curve groups in Figs. 27 and 30, it is seen, first from Fig. 27, that for a 2600-deg. flame temperature, a 10,000-B.t.u. coal will require an energy-release rate of 28,000. For a 6000-B.t.u. coal this must be increased to 42,000. The iso-transfer curves in Fig. 30 show that for these conditions the

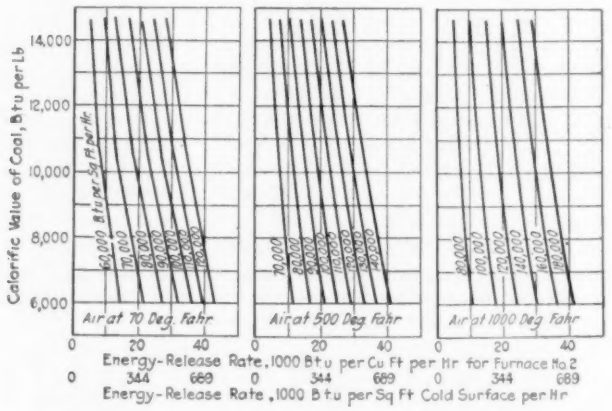

FIG. 30 INFLUENCE OF CALORIFIC VALUE OF COAL ON REQUIRED ENERGY-RELEASE RATE FOR A GIVEN RATE OF HEAT TRANSFER
(Furnace No. 2, Type A; 20 per cent excess air.)

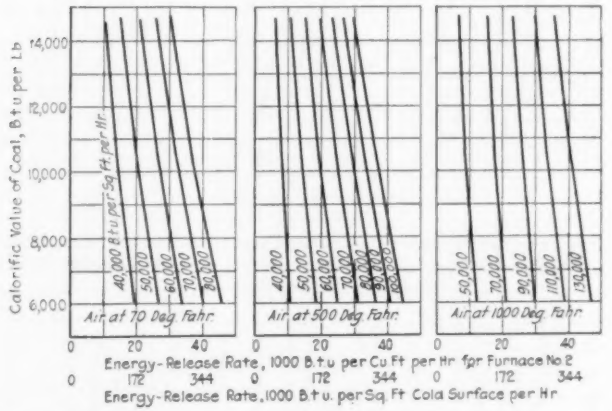

FIG. 31 INFLUENCE OF CALORIFIC VALUE OF COAL ON REQUIRED ENERGY-RELEASE RATE FOR A GIVEN RATE OF HEAT TRANSFER
(Furnace No. 2, Type B; 20 per cent excess air.)

rates of heat transfer are respectively 102,000 and 118,000 B.t.u. per sq. ft. of projected cold surface. This increase of 16,000 B.t.u. per sq. ft. per hour in the heat-transfer rate for the low-grade coal as compared with the high-grade coal, when the same mean flame temperature exists in both cases, is to be accounted for largely by the increased amount of radiation from the increased amount of water vapor, etc., in the products of combustion of the lower-grade coal. This difference, however, does not account for the total difference in energy quantities released in the furnace, as is obvious by comparing the two required energy-release rates: i.e., 28,000 as against 42,000. The remaining, and by far larger, part of the difference in total energy quantities released is thus absorbed in supplying heat to compensate for the differences in thermal capacities of the products of combustion of the lower-grade coal as compared with those of the higher-grade coal.

It may be said of the curves shown in Figs. 27 to 32 that they graphically portray the variation in radiation intensities to be expected in burning coals with respect to variation of calorific value of the coals, provided the actual composition of the range of coals under investigation does not depart too far from those considered here. It is apparent from an examination of Table 1 that the moisture and oxygen contents have been one of the chief variable factors. Should these constituents have remained very small in amount throughout the range and the B.t.u. content decreased almost wholly by an increase in the ash content of the coal, then unquestionably the trend of these curves would be somewhat different in the low-B.t.u. range. For instance, a 6000-B.t.u. coal might conceivably be composed of 0.41 lb. pure carbon and 0.59 lb. ash, in which case the products of combustion would be quite different from what they are for the 6000-B.t.u. coal here considered.

However, the composition of coal does not vary in this way. David White[14] made a study of more than 300 coals mined in the United States and has plotted several curves. One of his curves slopes from a high oxygen content and a low B.t.u. value to a low oxygen content and a high B.t.u. value. All points are

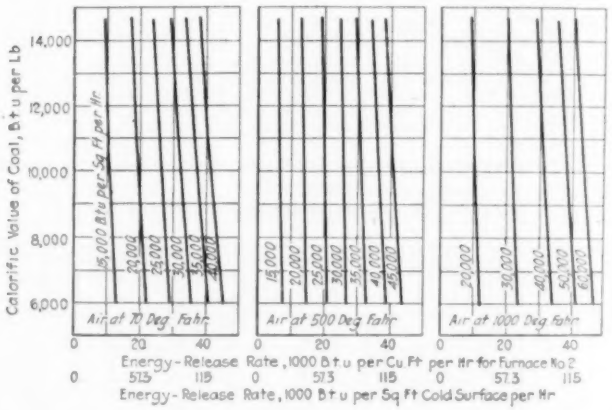

FIG. 32 INFLUENCE OF CALORIFIC VALUE OF COAL ON REQUIRED ENERGY-RELEASE RATE FOR A GIVEN RATE OF HEAT TRANSFER
(Furnace No. 2, Type E; 20 per cent excess air.)

within 2 per cent of falling on the curve. Another curve shows the carbon over the oxygen plus ash ratio to the B.t.u. value of the coal, and all points again fall within a 2 per cent accuracy. Again in general the moisture content of a coal bears a smooth-curve relation to the B.t.u. value of the coal. Thus it appears that the calorific value of a coal may be taken as a reasonably reliable determining factor for indicating what radiation intensities may be expected during combustion if, in evaluating these intensities throughout a range, representative coals in the several grades ranked according to their B.t.u. values are used as a basis for the calculations.

This concludes the authors' discussion of this subject. There have been no arguments for or against particular furnace arrangements or combustion methods. It is hoped that the information presented in curve form will be of some use to the engineer and may possibly aid him in determining what is and what is not a proper proportion. The curves are, it is thought, all fully titled, so that the uses to which they may be put are obvious. The most important information included appears in the form of the relativity of things. The absolute value of any result taken from the curves may be relied on only in so far as the conditions on which the analysis is based are realized in practice. The combustion reaction is a succession of energy transformations

[14] U. S. Bureau of Mines Bulletin No. 29 (1911).

which change so rapidly that they defy any attempt to follow its progress in minute detail, even though every change has its compensating reaction somewhere in the system. The theorist may only set up what he thinks from his knowledge and experience are the means or averages of the process, and, with this as a basis, work for average results. This is exactly what these data are, and no more.

Appendix No. 1

RELATION BETWEEN HEAT-TRANSFER RATE PER SQUARE FOOT OF SURFACE AND RADIATION ENERGY EQUATIONS

In Wohlenberg and Lindseth's paper the energy equation is given in the following form:[15]

$$dQ_U/dt + dQ_A/dt = dQ_B/dt + dQ_F/dt$$

Also

$$dQ_U/dt + dQ_A/dt = G_U U + G_A \Delta h_A$$

in which

$dQ_U/dt = G_U U$ = lb. of fuel per hr. $G_U \times$ B.t.u. per lb. fuel

$dQ_A/dt = G_A \Delta h_A$ = B.t.u. per hr. input above atmospheric temperature in G_A lb. air per hr. entering at temperature T_A

$dQ_B/dt = \Sigma G_B \Delta h_B$ = B.t.u. per hr. absorbed in raising ΣG_B lb. of gas per hr. from atmospheric temperature to mean flame temperature T_U, the symbol Σ denoting the several constituents

dQ_F/dt = B.t.u. per hr. absorbed at bare water-cooled walls in furnace envelope.

Let dq_F/dt = heat transfer B.t.u. per sq. ft. of projected cold surface in furnace envelope

S_C = square feet of projected cold surface in furnace envelope

μ_6 = fractional part of total input to furnace, B.t.u. per hr., which is transferred to cold furnace walls;

then

$$dq_F/dt = \frac{G_U U + G_A \Delta h_A}{S_C} \times \mu_6$$

and conversely

$$\mu_6 = \frac{S_C \times dq_F/dt}{G_U U + G_A \Delta h_A}$$

The quantity dq_F/dt is that shown as the ordinate scale in Figs. 17 to 24, and as a constant on the curves in Figs. 30, 31, and 32.

In arriving at values for the heat-transfer rate dq_F/dt, it is necessary to set up the energy equation for the conditions under investigation. This may be done in accordance with the method explained in Wohlenberg and Lindseth's paper. The flame temperature is arrived at by finding that value of it which makes the right- and left-hand sides of the energy equation equal to each other. This value of T_U determines the total heat dq_F/dt transferred to the cold walls, and hence also the unit heat-transfer rate dq_F/dt when the surface area S_C is known.

From the curves in Figs. 17 to 24 and 30 to 32 it is easy, by reversing the procedure, to determine both dQ_F/dt and μ_6. Thus

$$dQ_F/dt = dq_F/dt \times S_C$$

and

$$\mu_6 = \frac{dQ_U/dt}{\text{Flame volume} \times \text{energy-release rate} + \text{B.t.u. per hr. input above 70 deg. by preheated air}}$$

It should be remembered that the energy-release rate must be multiplied by the flame and not by the furnace volume in arriving at μ_6, because all figures on energy-release rate in this as well as the foregoing papers are based on the flame volume. For the furnace considered in this analysis the flame volume is 19 × 19 × 19 = 6859 cu. ft.

To facilitate heat-transfer computations for the zone beyond the furnace the thermal-capacity curves shown in Fig. 33 are included. Having determined the radiation mean of the flame temperature, which of necessity is equal to the mean temperature of the gases escaping from the furnace, reference to these curves at once shows how much heat is left in the products per pound of coal above a temperature of 70 deg. If the lower temperature is above 70 deg., as is generally the case, it is of course necessary to subtract the thermal capacity of the gases at this temperature as taken from the chart, from that for the flame temperature.

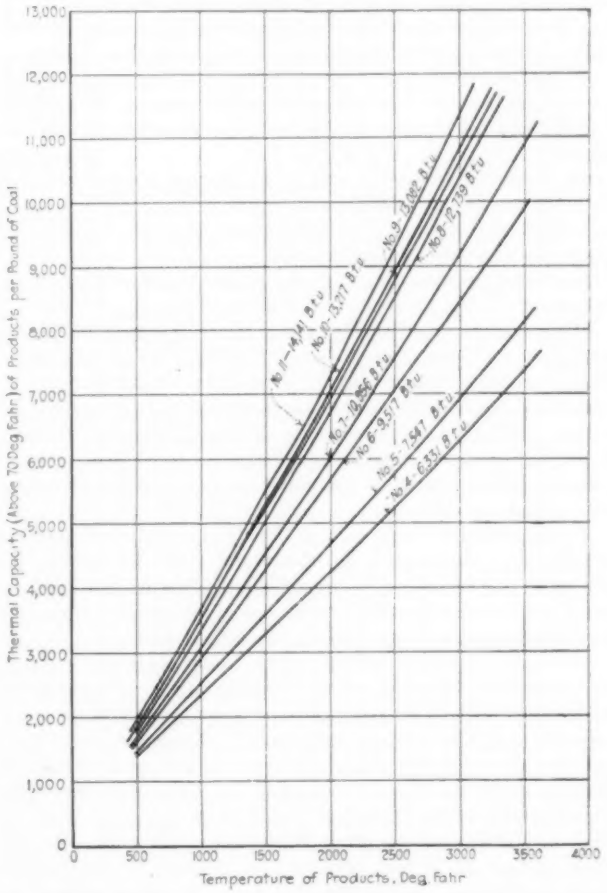

FIG. 33 THERMAL CAPACITY OF PRODUCTS OF COMBUSTION PER POUND OF COAL

(Excess air = 20 per cent for all curves.)

This difference represents the amount of heat to be withdrawn from the products of combustion per pound of coal in cooling them from flame temperature to the temperature in question.

Discussion

HENRY KREISINGER.[16] This paper contains the results of a large amount of theoretical calculations involving the rate of heat absorption by bare water-cooled surfaces exposed to radiation in furnaces burning various kinds of coal in pulverized form. Such calculations require much labor and patience, especially when so little experimental data are available and consequently many assumptions have to be made. The paper would have been more complete and more easily followed if the appendix had contained more detailed explanations of the factors used in computing the rate of heat absorption. That is, the last member of the energy equation DQF/DT should have been more fully explained. Without this explanation in the paper, one has to study other papers in order to get an understanding of what factors this member contains. On consulting the papers referred to one learns that this member contains the following factors:

(*a*) Radiation from the surface of the coal particles, corrected for the heat reflected from the water-cooled surfaces. This factor varies as the difference of the 4th powers of the absolute temperatures.

(*b*) Radiation from CO_2 and H_2O corrected for the heat reflected from the heat-absorbing surfaces. This factor is a function of the concentration, the thickness of the layer of these gases, and the absolute temperature.

(*c*) A convection factor, consisting of heat transferred by direct contact of the hot gases with the water-cooled surfaces.

The inclusion of all the foregoing factors requires many assumptions and complicates the calculations. Usually in problems of furnace design only the radiation from the flame is considered and a coefficient is assumed that will give approximately the total heat received by the heat-absorbing surfaces. In all such problems a great deal of judgment is required, and the calculated results must be compared with the few experimental results that are available.

We greatly need experimental data to check our theoretical calculations. At present the theoretical study is running far ahead of the experimental investigation. We do not need to check the theoretical study, but we should push the experimental investigation to catch up with the theoretical study.

The paper presents only the mean values such as the flame temperature and furnace-refractory temperature. This is about all one can calculate with any reasonable certainty. These mean temperatures must be studied along with the size of the furnace and the factor of fraction cold in order that one can arrive at the possible extremes of such temperatures. For example, with Pennsylvania bituminous coal and furnace one-third fraction cold, rate of energy release of 30,000 B.t.u. per cubic foot per hour, and air at 70 deg. fahr., the temperature of the furnace flame as shown in Fig. 7 is 2500 deg. fahr. In some parts of the furnace the temperature of the flame may be above 3000 deg., in other parts of the furnace below 2000 deg. In other words, the extremes may be well 1000 deg. apart. Similarly, the mean temperature for the furnace refractory for the same coal and the same conditions of combustion is given in Fig. 15 as 2100 deg. fahr. Assuming that the furnace is water-cooled at the top and bottom and is a perfect cube with a side of 20 ft., this furnace gives the fraction cold factor as one-third. The side walls, the front wall and the rear wall are made of refractory. The mean refractory temperature as computed is 2100 deg. fahr. Although this mean temperature may be nearly correct, the extremes are very far apart. The temperature half-way up the furnace along the side walls will be very nearly the temperature of the flame. The temperature near the water-cooled bottom and top will be approaching that of the water-cooled surfaces. That is, the temperature may vary from 1500 to 2500 deg. fahr. The part of the walls near the water-cooled top and bottom will be safe from abrasion, but half-way up the furnace the temperature may be too high for the refractory to stand it.

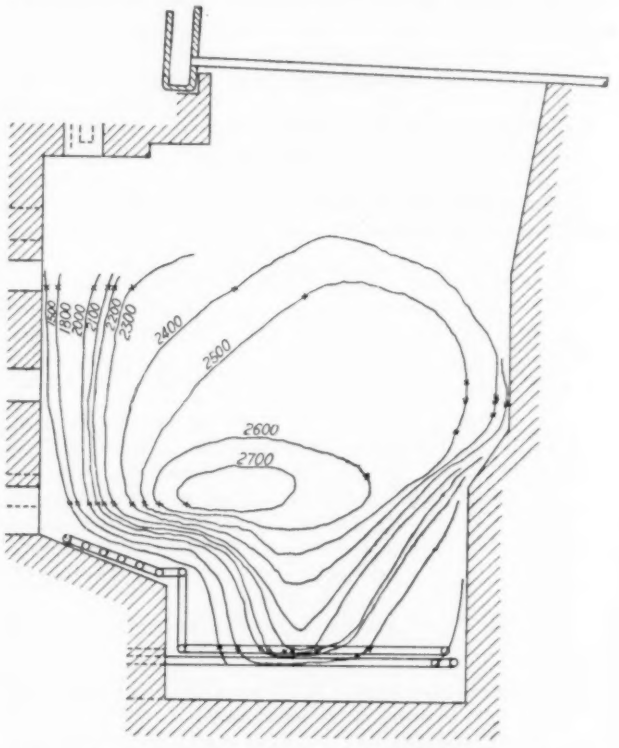

FIG. 34 FLAME TEMPERATURE IN POWDERED-COAL FURNACE WITH WATER-COOLED TOP AND BOTTOM

Fig. 34 shows the flame temperature in a powdered-coal furnace with water-cooled top and bottom. The fraction cold is 25 to 30 per cent. The rate of energy release was about 20,000 B.t.u. per hour. The temperature of the flame is shown to vary from about 1800 to 2700 deg. fahr. The mean temperature was probably 2100 deg. fahr. The temperatures were measured with a platinum couple consisting of a thin wire exposed to the furnace gases. The measurements are probably correct within 100 deg. fahr. The refractory of the side walls near the top and bottom were safe, but near the center of the furnace there was a bad abrasion from molten slag.

In the calculations of the furnace-flame temperatures the authors assumed that the flame filled the furnace to the same degree with all the rates of heat release. Actually this is never the case. At lower rates of combustion the flames fill only part of the combustion space nearest to the burners. Under such conditions the surface of the mass of flame is much smaller than it is when the flame fills the furnace completely. Since it is the surface of the flame which radiates most of the heat, the quantity of heat radiated from the flame at the low rates of combustion is smaller, not so much because of the lower flame temperature but because of the smaller flame surface radiating the heat. Thus the temperature of the flame at the low rates of combustion may not be much lower than it is at the high rates of combustion.

For example, a burning candle or a match placed in any part of a large completely water-cooled furnace will burn with a flame temperature of about 2200 deg. fahr., although the average rate of heat liberation based on the entire furnace volume may be

[16] Research Engineer, Combustion Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

less than 1 B.t.u. per cubic foot of combustion space per hour. Actually the combustion takes place in only a very small fraction of the furnace volume. The flame temperature of the candle or the match is high because the heat-radiating surface of the flame is very small and the heat radiated to the water-cooled walls from the flame surface is also very small. It is the extent of the flame surface and not the extent of the heat-absorbing water-cooled surface that determines the amount of heat radiated.

The average rate of heat liberation in combustion of pulverized coal can be reduced to 2000 B.t.u. per cubic foot per hour or even less in completely water-cooled furnace, provided the burners are of such a design that they produce proper mixing near the burner at such low rates of combustion. Usually at such low rates practically all of the air needed for combustion is supplied with the coal as primary air, and very little or no secondary air is used. Very little mixing takes place near the burner, and the coal is blown far into the furnace before ignition is started. In such cases it is the burner design that is responsible for the poor combustion results. If such burners produced as good mixing at the low rates of combustion as they do at the high rates, no difficulty would be experienced in good combustion results at the low rate of average heat liberation.

Much heat is radiated from a luminous and to a large extent opaque flame. In pulverized-coal furnaces such flame is produced by the combustion of the volatile matter of the coal. The volatile matter is driven from the coal as heavy hydrocarbons largely in the form of tar vapors. These heavy hydrocarbons are partly broken down by the heat into soot and light hydrocarbons and other light combustible gases. The lighter combustible gases burn first, the soot remaining in suspension as very tiny particles of incandescent carbon which give the flame its luminosity.

The authors call attention to the fact that the information presented in the paper is only relative, that is, it indicates how one factor affects another. The paper deals only with the means of averages of these effects. These means or averages form a basis upon which the actual temperatures can be estimated so that they can be given the right consideration in the design of a furnace.

After all, in the design of water-cooled furnaces the object of water-cooled surfaces is not to reduce the mean temperature below a certain point so that no fusion of ash would occur, but to place the water-cooled surfaces over the walls where destructive abrasion of refractory would take place. The calculated mean temperatures are of greater value in determining the location of the superheater and the extent of the superheating surface, and also in the calculation of the final temperature of the gases leaving the boiler so that the size of economizer or the air heater may be rationally determined.

G. H. Kaemmerling.[17] The authors have done a valuable service in compiling quantitative results of the application of radiation theory to a series of coal types which cover practically the entire heat-value range of usable solid fuels. The graphs presented make it possible to interpolate the radiation characteristics of nearly all commercial coals and lignites for various types of furnaces, and with the assistance of previous papers by Professor Wohlenberg, the complete range of furnace conditions for various fuel-air ratios may be determined.

It has been generally accepted in the design of furnaces for pulverized fuel that the intensity of combustion should be directly proportioned to the fusion temperatures of the ash. The present analysis demonstrates that the required variation in furnace performance between high-grade and low-grade fuels, as prescribed by ash-fusion points, has been overestimated.

[17] Technical Assistant to General Manager, Erie City Iron Works, Erie, Pa. Assoc-Mem. A.S.M.E.

In a recent paper before the International Bituminous Coal Conference, E. G. Bailey pointed out the fact that coal ash has not one, but a number of fusion points, which are all brought into action in the furnace and which may vary widely from the composite ash-fusion temperature. When this is considered in conjunction with the characteristics of fuels brought out in the paper under discussion, it becomes at least permissible to speculate whether or not the question of suiting furnace design to ash fusion becomes so complicated in proportion to its importance as to make it impracticable.

It may be supposed that space limitations and the large amount of work involved in its preparation compelled the authors of this paper to restrict their consideration to uncooled refractory walls and bare water-cooled walls, the characteristics of each being approximately constant as heat-absorptive surfaces. The entire range between these extremes may be represented by the refractory-covered water wall, in which the heat absorptive capacity is directly proportional to the thickness, and also to the conductivity, of the refractory covering the tubes.

It has been the writer's privilege to see something of the operation of a recent water-cooled furnace installation in which the water walls are covered with silicon-carbide refractories. The range of operation of the furnace varied from a heat release of 10,000 to over 50,000 B.t.u. per cu. ft., assuming that the flame and furnace volumes were identical, or somewhat higher if Wohlenberg and Anthony's assumption is used. The upper figure corresponded to a boiler rating of over 500 per cent, the rated horsepower of the boiler being 500. No difficulty was experienced with the ash throughout the range of operation, although a uniformly high CO_2 of 16 per cent or better was maintained at the highest combustion rates attempted. The walls were at all times covered by a thin layer of porous slag, which adhered to but did not penetrate the face of the refractory, and could be peeled off in sheets when the furnace was cold without leaving the slightest sign of deterioration on the refractory faces. No hard slag was deposited on the boiler tubes. This fact may be ascribed to the use of a novel vertical turbulent burner, which fired downward and away from the boiler tubes. There was no indication that the limit of practicable heat release had been reached at the maximum rates attempted, with respect to ash handling, wall life, or burner performance.

The heat-transfer curves presented by Wohlenberg and Anthony show clearly that the total heat absorption by the furnace walls is increased to a minor degree only by increase of the fraction cold, due to the rapid falling off of rate of heat transfer per square foot as the proportion of cold area increases. This results in a decrease in heat-absorption efficiency of all the cold surfaces, including the front bank of the boiler.

In view of the limitations imposed upon furnace performance and adaptability by the use of either uncooled refractory or bare tube walls, the performance of refractory-covered water walls such as described becomes a matter of very considerable importance, and we may look forward with interest to the analysis of furnace conditions with water-cooled refractory walls which the authors of the paper have promised us.

Authors' Closure

The authors wish to express thanks to Messrs. Kaemmerling and Kreisinger for including in their discussions of the paper some valuable suggestions.

Mr. Kaemmerling points out the discrepancies between ash-fusion temperatures made in the laboratory and the possible behavior of the ash in the furnace. He then expresses some doubt concerning the practicability of designing furnaces with reference to ash fusion. It should be emphasized in this respect that even though our knowledge of the subject is rather fragmentary, each

new fact, even though it may contain information which does no more than relate one mean condition to another, nevertheless furnishes another bench mark, as it were, on which good judgment may be based. Finally when the whole picture has been circumscribed by such bench marks, judgment passes out of the picture, a condition which is probably never realized in engineering. Judgment, however, to be of any value at all must begin by being based on certain such bench marks and that is the light in which the data included in this paper may be viewed.

Both Messrs. Kaemmerling and Kreisinger point to the importance of water cooling in furnace walls for the purpose of protecting the necessary refractory parts. Mr. Kreisinger mentions the furnace envelope composed of bare water-cooled walls and other walls of refractory. Mr. Kaemmerling presents data from tests of a furnace in which certain refractory walls are water cooled. Both types of furnace envelope probably have their place, and, as Mr. Kreisinger says, an object of furnace design is to provide water-cooled walls in such places as to protect the refractory walls.

The question might be asked, Why put in any refractory walls at all? This is a matter of providing hot surfaces to improve combustion conditions. Whether, then, a furnace provided with hot and cold spots or one provided with a whole hot surface but at a somewhat reduced temperature as compared to the hot-spot part of the other type of furnace is the better is a question which practice alone can determine. Load curve, coal type, size of furnace, etc. are conditions that would have to be considered in each case before coming to a decision.

List of A.S.M.E. Transactions Papers Published Since January 1, 1928

BELOW is published a complete list of the papers which have appeared in the various sections of Transactions since January 1, 1928, together with references to the issues of "Mechanical Engineering" in which abstracts of them may be found.

AERONAUTICS

	Issue and page of MECHANICAL ENGINEERING in which abstract was published
Progress in Aeronautics	June, '28, p. 496
Facilities for Research Work in Aeronautics in the United States	June, '28, p. 496
Oleo Gears for Aircraft, E. E. Aldrin	June, '28, p. 497
The Development of Large Commercial Rigid Airships, K. Arnstein	June, '28, p. 497
Metallurgy of Aircraft Engines, B. Clements	June, '28, p. 497
A New Propeller-Type, High-Speed Windmill for Electric Generation, E. N. Fales	June, '28, p. 497
Materials for Aircraft Parts Subject to High Temperatures, J. B. Johnson	June, '28, p. 497
Development of the Buffalo Airport, J. M. Satterfield	June, '28, p. 497
The Development and Technical Aspects of the Fairchild Caminez Engine, H. Caminez	Dec., '28, p. 974
An Introduction to the Problem of Wing Flutter, C. F. Greene	Dec., '28, p. 974
Combustion in Aircraft Oil Engines, W. F. Joachim	Dec., '28, p. 974
Cycloidal Propulsion Applied to Aircraft, F. K. Kirsten	Dec., '28, p. 974
Meteorological Service for Commercial Airways, C. G. Rossby	Dec., '28, p. 974
Air-Transport Engineering, L. D. Seymour	Dec., '28, p. 974
The Design of Commercial Airplanes, Max Short	Dec., '28, p. 975
Gluing Wood in Aircraft Work, T. R. Truax	Dec., '28, p. 975
The Oil Engine and Aeronautics, E. F. Wilson	Dec., '28, p. 975
The Problem of Solid Fuel Injection in High-Speed Flexible Oil Engines, A. C. Attendu	Mar., '29, p. 248
The Status of the Airship in America, Gilbert Betancourt	Mar., '29, p. 248
A Comparative Examination of the Airplane and the Airship, Carl B. Fritsche	Mar., '29, p. 249
The Theory of Long-Distance Flight, Robert J. Nebesar	Mar., '29, p. 249
Slotted Wings, F. Handley Page	Mar., '29, p. 249
Heavy-Oil Engines for Aircraft, H. R. Pye	Mar., '29, p. 249
Preparation of an Airline for Commercial Operations, J. G. Ray	Mar., '29, p. 249
Technical Development of the Reed Metal Propeller, S. Albert Reed	Mar., '29, p. 249
Modern Airports and Airport Planning, B. Russell Shaw	Mar., '29, p. 249
Some Economic Features Affecting Commercial Aviation, Carl E. Trube	Mar., '29, p. 249
Applications of Balsa Wood in Aircraft, G. L. Weeks, Jr.	Mar., '29, p. 249

APPLIED MECHANICS

Analysis of Strains and Stresses in a Wristpin of an Automobile Engine by the Mathematical Theory of Elasticity, G. B. Collier	April, '28, p. 338
An Investigation of the Performance of Waste-Packed Armature Bearings, G. B. Karelitz	April, '28, p. 338
Measurement of Flow of Air and Gas, S. A. Moss	April, '28, p. 338
Effect of Entrance and Discharge Angles on the Performance of a Centrifugal Fan, G. S. Wilson, W. L. Dudley, and H. J. McIntyre	April, '28, p. 338
Progress in Lubrication Research	April, '28, p. 339
Vibration of Frames of Electrical Machines, J. P. Den Hartog	Dec., '28, p. 975
The Theory of the Dynamic Vibration Absorber, J. Ormondroyd and J. P. Den Hartog	Dec., '28, p. 975
The Range and Severity of Torsional Vibration in Diesel Engines, F. P. Porter	Dec., '28, p. 975
Strength of Steel Columns, H. M. Westergaard and W. T. Osgood	Dec., '28, p. 975
A Simplified Method of Determining Stresses in Rotating Disks, M. G. Driessen	April, '29, p. 327
Vibration of Frames of Electrical Machines, J. P. Den Hartog	April, '29, p. 327
Evaluation of the Technical Worth of a Steel From Physical Test Data, A. B. Kinzel	April, '29, p. 327
Stresses in the Drive System of Three-Cylinder-Locomotives, Fritz Loewenberg	April, '29, p. 327
The Range and Severity of Torsional Vibration in Diesel Engines, Frederic P. Porter	April, '29, p. 327
Investigation of Insulated Walls, Frank B. Rowley	April, '29, p. 327
Stress Analysis in Electrical Rotating Machinery, M. Stone	April, '29, p. 327

FUELS AND STEAM POWER

Fuels, Past and Prospective, S. W. Parr	June, '28, p. 498
American Fuel Resources, O. P. Hood	June, '28, p. 498
Combustion and Heat Transfer, R. T. Haslam and H. C. Hottel	June, '28, p. 498
The High Cost of Fuel Saving, W. Trinks	June, '28, p. 498
Application of Powdered Coal to Small Boilers of Industrial Plants, Henry Kreisinger	June, '28, p. 498
The Clinkering of Coal Ash as Related to Laboratory Fusibility Determinations, A. C. Fieldner, W. A. Selvig, and P. Nicholls	June, '28, p. 498
Factors Governing the Purchase of Coal, M. B. Smith	June, '28, p. 498
Properties of Refractories and Their Relation to Conditions in Service, S. M. Phelps	June, '28, p. 498
Characteristics of Modern Boilers, E. R. Fish	June, '28, p. 498
Direct-Fired Powdered-Fuel Boilers With Well-Type Furnaces at Charles R. Huntley Station, H. M. Cushing and R. P. Moore	June, '28, p. 498
The Use of Fuels in Brick Kilns, W. E. Rice	June, '28, p. 498
Progress in Gas-Producer Practice, W. B. Chapman	June, '28, p. 498
The Burning of Liquid Fuels, E. H. Peabody	June, '28, p. 498
Automatic Combustion Control, T. A. Peebles	June, '28, p. 498
Characteristics of Modern Stokers, F. H. Daniels	June, '28, p. 498
The Economics of Air-Preheater Application, F. M. Van Deventer	June, '28, p. 498
Economics of Dry-Quenching Coke by the Sulzer Process, A. N. Beebee	June, '28, p. 498
The Preparation of Coal With Special Reference to Quality, William Beury	June, '28, p. 498
Railway Smoke Abatement, J. B. Irwin	June, '28, p. 498
The Measurement of Atmospheric Pollution, Visible and Invisible, G. T. Moore	June, '28, p. 498
Smoke-Abatement Methods Used in Cleveland, E. H. Whitlock	June, '28, p. 498
Organizing a Smoke-Abatement Campaign, Erle Ormsby	June, '28, p. 498
Smokeless and Efficient Firing of Domestic Furnaces, V. J. Azbe	June, '28, p. 498
The Effect of Atmospheric Smoke Pollution, A. S. Langsdorf	June, '28, p. 498
Progress in Fuel Utilization in 1927	Dec., '28, p. 976
Progress in Steam-Power Engineering	Dec., '28, p. 976
The Economics of Coal Carbonization in the United States, Geo. A. Orrok	Dec., '28, p. 976
The K.S.G. Process of Low-Temperature Carbonization, Walter Runge	Dec., '28, p. 976
Higher Steam Pressures, N. E. Funk	Dec., '28, p. 976
High-Pressure Steam at Edgar Station, I. E. Moultrop and E. W. Norris	Dec., '28, p. 976
High Steam Pressure and Temperature at Crawford Ave. Station, A. D. Bailey	Dec., '28, p. 976
High-Pressure Steam Boilers, Geo. A. Orrok	Dec., '28, p. 976
The Ruths Steam Accumulator, R. A. Langworthy	Dec., '28, p. 976
Some Operating Data of Large Steam-Generating Units, Henry Kreisinger and T. E. Purcell	Dec., '28, p. 976
Combination Firing of Blast-Furnace Gas and Pulverized Coal, F. G. Cutler	Dec., '28, p. 976
The Use of Pulverized Coal in Basic Open-Hearth Furnaces, E. L. Herndon	Dec., '28, p. 976
The Flow of Heat Through Furnace Hearths, J. D. Keller	Dec., '28, p. 976
Refractories Service Conditions in Furnaces Burning Powdered Illinois Coal With Long-Flame Burners, R. A. Sherman and Edmund Taylor	Dec., '28, p. 976
Some Fundamental Considerations in the Design of Boiler Furnaces, W. J. Wohlenberg and F. W. Brooks	Dec., '28, p. 976
Some Economic Factors in Power-Station Design, H. B. Brydon	Dec., '28, p. 976
Modernization of the Industrial Power Plant, C. G. Spencer	Dec., '28, p. 976
Engineering Analysis as Applied to the Selection of Type and Size of Power-Plant Equipment, J. N. Landis	Dec., '28, p. 976
The Reciprocating Dry-Vacuum Pump, W. S. Weeks and P. E. Letchworth	Dec., '28, p. 976
Power Consumption of Boiler-Feed Pumps, K. A. Mayr	Dec., '28, p. 976
Evaporators for Boiler-Feed Make-Up Water, W. L. Badger	Dec., '28, p. 976
Joint Research Committee on Boiler-Feedwater Studies	Dec., '28, p. 976
Arc-Welded Pipe Lines, W. L. Warner	Dec., '28, p. 976
The Welding of Power-Plant Piping, A. W. Moulder	Dec., '28, p. 976
Stresses and Reactions in Expansion Pipe Bends, A. M. Wahl	Dec., '28, p. 976
Properties of Ferrous Metals at Elevated Temperatures as Determined by Short-Time Tensile and Expansion Tests, A. E. White and C. L. Clark	Dec., '28, p. 976
Constitution and Classification of Coal, A. C. Fieldner	June, '29, p. 481
Burning Characteristics of Different Coals, Henry Kreisinger and B. J. Cross	June, '29, p. 481
Washing and Preparation of Coal, H. D. Smith	June, '29, p. 481
Progress Toward Direct Firing of Boilers With Producer Gas, William B. Chapman	June, '29, p. 481
Industrial-Furnace Efficiency, Economic Consideration, James H. Herron	June, '29, p. 481
The Use of Fuels in Tunnel Kilns, W. E. Rice	June, '29, p. 481
Recent Developments and Improvements in the Baffling of Vertical Boilers, A. C. Danks	June, '29, p. 481
Present Tendency of Boiler-Water Conditioning, R. E. Hall	June, '29, p. 481
Collecting the Dust From Chimney Gases of Powdered-Fuel Installations, K. Toensfeldt	June, '29, p. 481

	Issue and page of MECHANICAL ENGINEERING in which abstract was published
Fineness of Pulverized Fuel as Affected by Mill Types, Lincoln T. Work	June, '29, p. 482
Unit System of Coal Pulverizers for the Generation of Steam, John Blizard	June, '29, p. 482
The Need for Coal Research, F. R. Wadleigh	June, '29, p. 482
Determination of Economic Value in the Selection of Power-Plant Equipment, F. M. Van Deventer	June, '29, p. 482
Boiler-Furnace Refractories, C. F. Hirshfeld and W. A. Carter	June, '29, p. 482
Stoker Advantages and Disadvantages, Theodore Maynz	June, '29, p. 482
Pulverized-Coal Firing of Marine Water-Tube Boilers, T. B. Stillman	June, '29, p. 482
The Economic Status of Oil as a Fuel for Marine Service, George Atwell Richardson	June, '29, p. 482
Railway Practices in Utilization and Conservation of Oil, J. N. Clark	June, '29, p. 482
Selection and Use of Fuels in Locomotive Practice, Malcolm Macfarlane	June, '29, p. 482
Development and Recent Design of Stoker-Fired Equipment for Steam Generation, Joseph G. Worker and Joseph S. Bennett	June, '29, p. 482
Progress in Central-Station Use of Pulverized Coal, E. H. Tenney	June, '29, p. 483
Present Status of Furnace and Burner Design for the Use of Pulverized Fuel, E. G. Bailey	June, '29, p. 483
The Relative Value in Locomotive Service of Different Sizes of the Same Coals, John G. Crawford	June, '29, p. 483
Railway Practice in Utilization and Conservation of Coal, W. J. Overmire	June, '29, p. 483
Damage Due to Smoke, H. B. Meller	June, '29, p. 483
Smokeless and Efficient Firing of Domestic Furnaces—Part II, Victor J. Azbe	June, '29, p. 483
Problems and Methods in Smoke-Abatement Work, H. K. Kugel	June, '29, p. 483
Some Factors in Furnace Design for High Capacity, E. G. Bailey	June, '29, p. 483
An Accurate Method for Measuring Steam, Axel Härlin	June, '29, p. 483
A Graphical Method of Computing Boiler Heat Balance, Eric Pick	June, '29, p. 483
Refractories Service Conditions in Furnaces Burning Fuel Oil. Progress Report of the A.S.M.E. Special Research Committee on Boiler-Furnace Refractories, R. A. Sherman, Edmund Taylor, and H. S. Karch	June, '29, p. 484

HYDRAULICS

Centrifugal Pumps, H. T. Davey	April, '28, p. 340
A Method of Analyzing the Performance Curves of Centrifugal Pumps, J. Lichtenstein	April, '28, p. 340
A New Method of Separating the Hydraulic Losses in a Centrifugal Pump, M. D. Aisenstein	April, '28, p. 340
Progress in Hydraulics	April, '28, p. 340
Computation of the Tail-Water Depth of the Hydraulic Jump in Sloping Flumes, Robert W. Ellms	June, '29, p. 484
Notes on "A New Method of Separating the Hydraulic Losses in a Centrifugal Pump," Michael D. Aisenstein	June, '29, p. 484
Friction in Dredge Pipes, James H. Polhemus and John R. DuPriest	June, '29, p. 484
Flow of Water Over a V-Notch, Joseph Tarrant	June, '29, p. 484

IRON AND STEEL

Progress in the Iron and Steel Industry	June, '28, p. 498
Developments in 4-High Rolling Mills, F. G. Biggert, Jr.	June, '28, p. 498
Destruction Test of a 66-In. Forged Steel Penstock Pipe, J. L. Cox	June, '28, p. 498
Physical Properties of Alloy Steels Under Various Heat Treatments and at Elevated Temperatures, C. B. Callomon	Dec., '28, p. 976
The Use of Pulverized Coal in Basic Open-Hearth Furnaces, E. L. Herndon	Dec., '28, p. 976
Recent Developments in the Use of Nickel Steel, C. McKnight	Dec., '28, p. 976
The Manufacture of Seamless Tubes, R. C. Stiefel and G. A. Pugh	Dec., '28, p. 976
Mechanical Properties of Aluminum Casting Alloys at Elevated Temperatures, R. L. Templin, C. Braglio, and K. Marsh	Dec., '28, p. 977

MACHINE-SHOP PRACTICE

Progress in Machine-Shop Practice	Aug., '28, p. 657
The Development of Machine Tools From a User's Viewpoint, F. C. Spencer	Aug., '28, p. 657
Plant Maintenance, G. H. Ashman	Aug., '28, p. 657
Plant Maintenance and Return on Capital Investment, W. H. Chapman	Aug., '28, p. 657
Maintenance of Shop Equipment, J. R. Weaver	Aug., '28, p. 657
Maintenance of Machine Equipment at the National Cash Register Company's Plant, W. Hartman	Aug., '28, p. 657
Maintenance of Shop Equipment, C. S. Gotwals	Aug., '28, p. 657
Characteristics of Hydraulic Feed and Drive for Cutting Tools, W. Ferris	Aug., '28, p. 657
Hydraulics and Modern Machine-Tool Design, W. J. Guild	Aug., '28, p. 657
Hydrauiic Feeding Mechanism for Milling Machines, S. Einstein and H. Ernst	Aug., '28, p. 657
The Development of Hydraulic Feeds on Multiple Drilling Machines, R. M. Galloway	Aug., '28, p. 657
The Economics of Machine-Tool Replacement, M. S. Curtis	Aug., '28, p. 658
The Prerequisites of Successful Polishing, B. H. Divine	Aug., '28, p. 658
Shop-Equipment Policies in Representative Plants, L. C. Morrow	Aug., '28, p. 658
Recent Developments in the Application of Anti-Friction Bearings to Machine Tools, R. F. Runge	Aug., '28, p. 658
The Manufacture and Application of Extruded Copper Tubes, G. A. Foisy	Aug., '28, p. 658
Ball-Bearing Machine-Tool Spindles, T. Barish	Dec., '28, p. 977
A Study of Tin-Base Bearing Metals, O. W. Wells and G. B. Karelitz	Dec., '28, p. 978
The Design and Building of Jigs and Fixtures, F. P. Hutchison	Dec., '28, p. 978
Maintenance of Machine Tools, J. C. Mattern	Dec., '28, p. 978
Maintenance in the Large Industrial Plant, C. M. Thompson	Dec., '28, p. 978
Inspection Methods and Quality Control in the Manufacture of Aircraft-Engine Parts, Hugh W. Roughley	Mar., '29, p. 249
High-Speed Gearing, Ira Short	Mar., '29, p. 249
The Pratt & Whitney Gear-Shaving Process, H. D. Tanner	Mar., '29, p. 249
Some Practices in the Use of Machine Tools in the Electrical Industry, J. R. Weaver	Mar., '29, p. 249

MANAGEMENT

Progress in Management Engineering	July, '28, p. 579
Production-Control Methods in the Rubber Industry, F. B. Calhoun	July, '28, p. 579
Coordinating Wage Incentives and Production Control, D. B. Charters	July, '28, p. 579
Production Control in a Wrought-Brass Mill, W. R. Clark and A. Brewer	July, '28, p. 579
Some Essential Principles for Budgetary Control, H. V. Coes	July, '28, p. 579
Budgetary Control, J. P. Jordan	July, '28, p. 579
Determination of Minimum-Cost Purchase Quantities, R. C. Davis	July, '28, p. 580
Control of Quality, W. W. Graper	July, '28, p. 580
Coordinating Wage Incentives and Production Control, O. Grothe	July, '28, p. 580
Control of Factory Overhead, H. G. Perkins	July, '28, p. 580
Economic Production Quantities, F. E. Raymond	July, '28, p. 580
Training Minor Executives in a Rapidly Growing Organization, A. J. Beatty	Feb., '29, p. 171
Systems of Workman Payment in Porcelain Factories, Hobert M. Kraner	Feb., '29, p. 171
The Control of Quality in a Manufactured Product, James H. Marks	Feb., '29, p. 171
The Apprenticeship-Traning Program of the Tri-City Manufacturers, S. M. Brah	April, '29, p. 327
An Industrial-Plant-Location Study, Emmett B. Carter	April, '29, p. 327
Manufacturing and Wage-Payment Methods as Practiced by the Hall-Scott Motor Car Company, Alfred B. Celander	April, '29, p. 327
Motion-Study Principles and Their Application in a Department Store, B. Eugenia Lies and Marie P. Sealy	April, '29, p. 327
An Application of Motion Study to Group Work in Industry, J. A. Piacitelli	April, '29, p. 328
The Work Required to Operate Several Makes of Typewriters, F. H. Norton	April, '29, p. 328

MATERIALS HANDLING

Progress in Materials Handling	June, '28, p. 498
Sugar-Warehouse Conveying Systems, J. T. Buzzo	June, '28, p. 498
Operating Costs of Electrical Industrial Trucks and Tractors, C. B. Crockett and H. J. Payne	June, '28, p. 499
Materials Handling as an Aid to Production, F. L. Eidmann	June, '28, p. 499
Cargo Cranes—Types Available, Factors Governing Selection, and Latest Developments, B. Dunell	June, '28, p. 499
Bulk-Material Handling at Docks and Storage Plants, A. F. Case	Feb., '29, p. 171
Fundamental Principles in Materials Handling, Harold Vinton Coes	Feb., '29, p. 171
A Materials-Handling and Transport Organization, C. A. Fike	Feb., '29, p. 171
Handling Methods and Equipment in a Large Mail-Order House, H. E. Odenath	Feb., '29, p. 171
Modern Handling in Enameling Work, E. D. Smith	Feb., '29, p. 171
Marine Terminal Operation, Willard C. Brinton	June, '29, p. 484
The Hydraulic Handling of Ashes, Arthur Mellor Quinn	June, '29, p. 484
Modern Handling Methods of Railroad Transportation, G. C. Woodruff	June, '29, p. 484

OIL AND GAS POWER

The Study of Oil Sprays for Fuel-Injection Engines by Means of High-Speed Motion Pictures, E. G. Beardsley	April, '28, p. 339
Efficiencies of Otto and Diesel Engines, F. O. Ellenwood, F. C. Evans, and C. T. Chwang	April, '28, p. 339
Diesel Engines for Locomotives, R. Hildebrand	April, '28, p. 339
Oil-Spray Investigations of the N.A.C.A., W. F. Joachim	April, '28, p. 339
Experimental Combustion Chambers Designed for High-Speed Diesel Engines	April, '28, p. 339
Progress in Oil- and Gas-Power Engineering	April, '28, p. 340
Manufacture of Diesel Fuel Injectors, C. R. Alden	Feb., '29, p. 171
European Diesel-Engine Developments, O. F. Allen	Feb., '29, p. 172
Cooperative Diesel-Engine Research, Harte Cooke	Feb., '29, p. 172
Diesel-Fuel-Oil Specifications, G. H. Michler	Feb., '29, p. 172
The Economic Field for Large Diesel Engines, Edward B. Pollister	Feb., '29, p. 172
Oil-Spray Research at Penn State, P. H. Schweitzer	Feb., '29, p. 172
Specialization in Manufacturing Diesels, O. D. Treiber	Feb., '29, p. 172
The Diesel Engine and Public Utilities, Roswell H. Ward	Feb., '29, p. 172

	Issue and page of MECHANICAL ENGINEERING in which abstract was published
PRINTING INDUSTRIES	
Pumping Problems in Paper Mills, Helmer N. Anderson	Mar., '29, p. 250
Pulp-Grinder Control Reduces Paper Costs, Adolph F. Meyer	Mar., '29, p. 250
Engineering in the Printing Industries, Edward T. Miller	Mar., '29, p. 250
PETROLEUM	
Progress in the Petroleum Industry	Oct., '28, p. 814
General Heat-Transfer Formulas for Conduction and Convection, E. R. Cox	Oct., '28, p. 814
The Gas Lift as Applied to Oil Production, F. W. Lake	Oct., '28, p. 814
The Degree-Day Method of Fuel-Consumption Analysis, W. R. Abbott	Mar., '29, p. 250
Distillation and Fractionation in the Petroleum Industry, H. R. Swanson	Mar., '29, p. 250
The Construction and Protection of Oil and Natural-Gas Pipe Lines, W. H. T. Thornhill	Mar., '29, p. 250
One Example of Centrifugal Pumps for Petroleum Transportation, F. E. Warterfield, Jr.	Mar., '29, p. 250
RAILROAD	
Progress in Railroad Mechanical Engineering	Sept., '28, p. 735
The Mechanical Engineer in the Railroad and Railroad-Supply Industries	Sept., '28, p. 735
Can Accident Prevention Be Reduced to a Science? T. H. Carrow	Sept., '28, p. 735
High Steam Pressures in Locomotive Cylinders, L. H. Fry	Sept., '28, p. 735
Back Pressure and Cut-Off Adjustment for the Locomotive, T. C. McBride	Sept., '28, p. 735
Heating and Ventilating of Passenger Cars, E. A. Russell	Sept., '28, p. 735
The Motor Truck and L.C.L. Freight, F. J. Scarr	Sept., '28, p. 736
High Steam Pressure and Condensing Exhaust for Locomotives, J. M. Taggart	Sept., '28, p. 736
Vibration of Bridges, S. Timoshenko	Sept., '28, p. 736
Electric Interlocking System, R. J. Cullen	April, '29, p. 328
Locomotive and Freight-Car Utilization, C. B. Peck	April, '29, p. 328
Car Retarders, A Recent Development in Railway-Yard Operation, L. Richardson	April, '29, p. 328
Locomotive Sparks, L. W. Wallace	April, '29, p. 328
TEXTILES	
Increasing the Production of Cotton Padders, R. Longfield	Dec., '28, p. 977
The Value of Water in Textile Mills for Purposes Other Than Water Power, C. T. Main	Dec., '28, p. 977
Comparative Performance of Looms With Plain and Roller Bearings, G. H. Perkins	Dec., '28, p. 977
WOOD INDUSTRIES	
Progress in Woodworking Industries	June, '28, p. 499
Increasing the Production of Woodworking Machines by Use of Direct-Connected Alternating-Current Motors, W. A. Furst	June, '28, p. 499
The Pulp and Paper Industry and the Northwest, C. C. Hockley	June, '28, p. 499
Lacquer and Varnish Films, P. S. Kennedy	June, '28, p. 500
Investigation of the Pulp and Paper Industry in the State of Washington, B. W. Ross and S. Konzo	June, '28, p. 500
Improvements in Handling Methods in the Woodworking Industry, R. K. Merrill and G. H. Roderick	June, '28, p. 500
Static Loads Upon Bus Bodies, C. B. Norris and J. A. Potchen	June, '28, p. 500
Change in Moisture Content of Lumber During Rail Shipment, G. E. French	Dec., '28, p. 813
The Need of Research on Tropical Woods Before Marketing Them, A. Koehler	Dec., '28, p. 813
Our Need for Knowledge of Tropical Timbers, S. J. Record	Dec., '28, p. 814
Problems of Design for Mass Production in the Furniture Industry, B. E. Richardson	Dec., '28, p. 814
Compressive Tests of Balsa Wood, A. H. Stang	Dec., '28, p. 814

FSP-51-37

Analysis of Heat Absorption in Boilers and Superheaters

By N. ARTSAY,[1] NEW YORK, N. Y.

MANY questions in boiler design, remodeling, and operation control require the knowledge of heat absorption in every part of the heating surface. Proper proportioning and placing of the superheaters, and estimates of performance of new types of boilers will also be helped by a method permitting an easy calculation of heat absorption in, say, each row of boiler tubes, including also the radiant surfaces.

Theory of heat exchange in boilers is scattered over a multitude of papers and articles; the basic ideas in them are conflicting; actual data of heat transfer pertain to tests on single tubes elaborated by different methods, while the data for total boiler surface cannot be used due to the inclusion of the radiant heat absorption. So far the author has not seen a uniform method of calculating heat absorption going from the radiant surface through the consecutive rows of boiler tubes, superheater tubes, and the last-pass rows, which would be simple enough for quick checking of tests, or inversely, which would be convenient for estimation of probable test results. Therefore the author feels justified in offering a method which permits calculation of heat absorption, row by row, or by tube banks from the radiant surface to the last row of tubes, and which contains only one basic empirical constant. This constant is valid theoretically for radiant surface as well as for the convection surfaces because it is arranged to represent the constant of molecular energy transformations in the outermost atomic layer of the water-cooled metal.

The principle of hydrodynamic analogy was extremely fruitful in the theory of elasticity in electrodynamics, and in the questions of heat transfer. The late Prof. Groum Grjymailo created a theory of furnaces on principles of hydrodynamics. All these applications are only different aspects of the more general theory of energy transformations between the potential and kinetic form. The cases where the law of dynamic similitude offer practical solutions of extremely complicated problems are innumerable, it is sufficient to mention the hydraulic testing laboratories, the experimental tanks for ship models, the aerodynamical laboratories, the experiments on underwater explosions, etc. Hence an attempt is made here to combine the hydrodynamic analogy and the law of similitude for the problems of heat absorption in boilers.

Radiation Absorption

Taken up seriously since the advent of powdered-coal firing, the question of radiant-heat absorption was dealt with by two different schools of engineering thought.

The more mathematically inclined school considers the radiation absorption with the aid of physical laws of radiation; the solutions are extremely complicated and transcend the power of the average engineer to handle the question with a quantitative discernment. The beauty of the Stefan-Boltzmann formula appeals to everybody, but in the hands of the multitude the formula is misused very much. In all these calculations the starting point taken is the "furnace temperature," which is often considered the same as that of the furnace gas. The author emphatically stresses the point that the furnace temperature is almost entirely irrelevant to the question of total radiation absorbed. It must be well understood that the furnace-gas temperature represents the residual heat after the fact that a certain amount of combustion radiation was absorbed.

This school, moreover, cannot avoid the serious source of errors in the highly questionable values of this temperature, and the latter enter in the fourth power.

The second school takes a more direct way and considers the radiation absorption from the standpoint of energy exchange. Orrok with his broad view on the boiler-furnace phenomena, and his flair for empirical relationships offered a modification of Hudson's formula for calculating the fraction of total available sensible heat cut off at the moment of combustion by the radiant-heating surfaces. This beautiful conception of the instantaneous transfer of radiant energy from the molecules of carbon and hydrogen combining with the molecules of oxygen to the water-cooled metal together with the simultaneous reradiation of the unabsorbed energy is in conformity with present quantum theories. The author had an opportunity to check Orrok's formula in the case of the Benson high-pressure boiler test where it was feasible to separate the total radiant-heat absorption, and the result was correct in a wide range of rating.

Convection

Next comes the convection with the very questionable furnace-gas temperature as the starting value. The heat-transfer formulas with their fractional powers for mass-flow velocities have no physical interpretation, the experimental values do not cover the whole furnace-gas range, and the extrapolations are of doubtful reliability. The placement and extent of heating surface of the superheaters is still more or less guesswork in spite of the immense amount of observed values.

The author offers to treat the heat-exchange problem from the standpoint of energetics. Instead of calculating temperatures and rates of heat transfer, the fractions of available heat content in one pound of gas absorbed by each stage is calculated, the first stage being the radiant surface, and the next stages the consecutive rows or banks of tubes. Thus the boiler in this sense may be regarded as a turbine, but without transformation of heat into mechanical energy, the equivalent of the latter being the heat transmitted to water or steam.

It is very fortunate that as explained in Appendixes 1 and 2, the interchange of heat energy in a boiler is analogous to the work of a fluid in a turbine. The validity of the law of similitude in hydrodynamics allows the writing of equivalent formulas for radiation and convection with the same intrinsic value of the single constant. For convection the value of the constant is changed in accordance with the changed number of active gas molecules. In radiation only the combining molecules of the fuel (C, CO, H_2, S) are effective, while in convection all the molecules of the gas are effective.

Formulas. The derivation of formulas for radiation and convection is given in the Appendixes 3 and 4. Let us denote:

H_o = total sensible heat in B.t.u. available in one pound of gas above the saturated-steam temperature, the heat

[1] Assistant of Geo. A. Orrok, Consulting Engineer, New York, N. Y.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the society.

being calculated after combustion but before radiation absorption. It is obtained from the calorific value of the fuel by deduction of H_2, H_2O, CO and unburned-carbon losses, and of the heat content between the inlet air and the saturation temperatures.

S_r = projected surface exposed to radiation, sq. ft.

q = weight of fuel burned in the furnace, lb. per sec.

Then the fraction μ_1 of H_o absorbed as radiant heat:

$$\mu_1 = \frac{1 + a}{1 + \frac{35\,(fq)^{2/3}}{\sqrt{S_r}}} \quad \ldots\ldots [1]$$

In this formula

$a = \frac{0.22\ T_s}{H_o}$; T_s = saturation temperature deg. fahr. absolute;

f = fuel factor.

For any fuel, $f = \frac{1}{8.67}\left(\frac{C}{12} + \frac{H_2}{2} + \frac{CO}{28} + \frac{S}{32} + \frac{H_n + C_m}{n + 12_m}\right)$ where the chemical symbols denote respective percentages of these constituents in the fuel analysis on the "as fired" basis. The constant in Formula [1] is selected in such a way that for "good bituminous coal" $f = 1.0$. For other fuels the factor f varies widely. For instance:

Anthracite		Good Bituminous Coal		Lignite	
H_2	2.23%	H_2	4.3%	H_2	2.5%
C	79.22%	C	78.0%	C	36.6%
S	0.54%	S	0.5%	S	0.6%
$N_2 + O_2$	18.01%	$N_2 + O_2$	4.8%	$N_2 + O_2$	10.0%
Ash		Ash	8.0%	Ash	10.3%
Moisture		Moisture	4.4%	Moisture	40.0%
$f = 0.892$		$f = 1.00$		$f = 0.498$	

Fuel Oil		Natural Gas		Blast-Furnace Gas	
C	85.00%	CO	1.97%	H_2	0.07%
H_2	12.30%	C_2H_4	1.37%	CO	26.00%
S	1.75%	C_2H_6	7.89%	CO_2	17.10%
$N_2 + O_2$ =	0.95%	CH_4	85.30%	N_2	56.80%
		H_2	1.63%		
		$CO_2 + O_2$	1.90%		
$f = 1.532$		$f = 0.759$		$f = 0.11$	

Coke (90 per cent C) $f = 0.865$

Acetylene (100 per cent C_2H_2) = 0.444

Hydrogen (100 per cent H_2) = 5.76

The analysis given is by weight for all fuels. Thus the fuel factor corrects the fuel weight according to the relative number of combustible molecules.

If the ultimate analysis of coal on "as fired" basis is not available, $f = C/0.83$ where C is the combustible fraction of the coal from the proximate "as fired" analysis.

A closer investigation of the Formula [1] will show that the rate of heat absorption is independent of the saturation temperature, indicating that the combustion radiation is superimposed on the saturation temperature level. In case of refractory-lined blocks covering the water-cooled surfaces, the reduction in the rate of radiant-heat absorption will be due to the surface atomic layer of the refractory which is restoring its radiation-absorbing ability much more slowly than the metals, and also due to the somewhat smaller number of atoms on a unit of surface. Thus for the refractory-lined blocks the constant in Formula [1] is different, also the furnace temperature will be higher. The corrections are given in Appendix 5. From the quantum theory it follows also that at the surface exposed to combustion radiation, the convection heat transfer is zero.

To calculate the heat absorption by convection in a boiler, the boiler must first be divided into consecutive stages or zones. The way of dividing the total heating surface is indicated in Appendixes 6, 7, and 8 where the tests of a straight-tube B. & W., a Stirling, and a Scotch marine boiler are checked. One of the stages of convection is the superheater. The available heat content in the gas H is reduced for this stage due to the higher temperature of metal. The correction for one pound of gas is simple: H corrected $= H - \frac{0.25\,(t - t_s)}{2}$ where

t = superheated steam temperature, outlet

t_s = saturated steam temperature, inlet.

The heat transfer by convection is in general so low that the temperature gradient through the metal can be neglected. The initial heat content above saturation temperature in gas entering the first convection stage H_c is easily found after deduction of the radiant heat absorption from H_o.

$$H_c = (1 - \mu_1)\, H_o$$

Let us denote further:

H_n = B.t.u. per pound in gas entering the nth convection stage (nth row of tubes for instance). The value of H_n corresponds to heat content above the saturation temperature

μ_{cn} = fraction of H_n possible to absorb in the nth convection stage

H_{an} = heat B.t.u. per lb. of gas absorbed by the nth stage

S_{cn} = total heating surface in sq. ft. of the nth convection stage, parts of the tubes between the baffles

G = gas flow by weight, pounds per second

e = enclosure factor.

For plain tubes and cross flow of gas

$$e = \frac{1}{1 + \frac{l - d}{\pi d}}$$

l = pitch of tubes

d = outer diameter of tubes.

For tubes with extended surface and crossflow

$$e = \frac{1}{1 + \frac{S_g}{S_c}}$$

S_g = gas passage in sq. ft.

S_c = total heating surface, sq. ft.

For banks of tubes with parallel flow of gas, $e = 1.0$.

As derived in Appendix 4,

$$\mu_{cn} = \frac{1}{1 + \frac{C}{\sqrt[4]{\mu_{cn}}}} \quad \ldots\ldots [2]$$

for which:

$$C = \frac{18.5\,(eG)^{2/3}\,\sqrt[4]{1 + aH_o/H_n}}{\sqrt{S_{cn}}} \quad \ldots\ldots [3]$$

$$H_{an} = e\mu_{cn}\, H_n \quad \ldots\ldots [4]$$

First C is calculated from [3], then from the graph of solutions given on the diagram Fig. 3, μ_{cn} is read, and finally H_{an} is computed. The direct solution of [2] is too complicated but the graph gives the direct reading.

The majority of boilers contain many consecutive rows of tubes, and to avoid excessive arithmetic several rows may be taken at once by averaging S_c, and assuming an intermediate

value for H_n, the error thus made will be insignificant. If for one averaged row,

$$H \text{ absorbed} = \eta H_n$$

where η is calculated from [2], [3], and [4], then for m rows:

$$H_a = H_n [1 - (1 - \eta)^m] \quad [5]$$

where H_a is the heat absorbed per pound of gas by m rows, and H_n is heat content in one pound of gas entering the first of the m rows of tubes.

For the coal-fired boilers it is advisable to reduce the heating surface by about 20 per cent to account for the accumulation of flying ash or soot. For all fuels and types of heating surface it is recommended to take only the surface actually swept by the gases, neglecting the dead pockets.

The checking of boiler tests given in the Appendixes 6, 7, and 8 shows a fair agreement between the calculated and the observed values. It is easy to show that steam boilers in general transmit to water a very large fraction of the sensible heat in gas available above the saturation temperature; it runs 90 to 99 per cent depending upon the rating and degree of tube cleanliness. This figure, varying very little, may be linked by some simple function with the rating or any other valuation of the rate of steaming, and consequently the need for the aforesaid method may be questioned from the standpoint of overall performance. But most interesting things are learned from the distribution of heat absorption between different parts of the heating surface including superheaters, and it is here that the usefulness of the method comes in.

Appendix 1—Energy Transfer by Radiation and Convection

The method elaborated here is planned on the following lines in conformity with the quantum theories of radiation which regard a quantum of energy as dynamically definite entity, a "molecule of energy."

When the combustible molecules of a fuel combine with the corresponding number of oxygen molecules, certain quanta of energy are simultaneously radiated in all directions. These quanta are large compared with the quanta which are being absorbed, and reradiated by the furnace gas and refractories, and being far less numerous they are "crowded out" on the excited molecules of gas and refractories. Hence, these large quanta suffer multiple reflections, and only when they strike, during the reverberations, the water-cooled metal surface which is continuously restoring its absorbing ability, a fraction of every one of them is absorbed, while the remaining radiant energy, in reduced quanta produces the thermal level of the furnace through the medium of CO, CO_2, and H_2O. The important point is that the time during which the large combustion quanta are many times reflected by the molecules (excited to the furnace quantum level) is many millions of times shorter than the time during which the part of generated gas is present in the furnace. Hence, *all the combustion quanta radiated are reflected from the gaseous molecules; they will reach successively every square unit of the furnace envelope in a time very short compared with the presence of the generated gas in the furnace, and also every quantum of combustion radiation will eventually strike the surface of water-cooled metal.* The proof of the statement in italics by the quantum theory would be too complicated, but a simple calculation will indicate its plausibility.

A furnace 20 × 20 × 20 ft. will have a volume of 8000 cu. ft. and a projected surface of 2400 sq. ft. At usual furnace temperatures there are roughly 1.5×10^{20} molecules of gas per cubic foot while each square foot of metal exposes roughly 1.82×10^{16} atoms of iron. Hence every quantum wave train of radiation reverberating in the furnace has to pass each time 1.2×10^{24} molecules of gas, and to reflect from 4.3×10^{19} atoms of iron and refractory. The absorbing ability of gaseous molecules here is apparently many million times less than the absorbing ability of the metal walls. However, it is known that their absorbing abilities are of the same order, and hence this result can be explained only by the assumption that the gaseous molecules are busy with the smaller, but much more numerous, quanta of gaseous and refractory radiation and therefore unable simultaneously to absorb and reradiate the large combustion quanta. In other words, it may be stated that *the furnace gas is in a degree opaque to the gaseous and refractory radiation of the furnace-temperature level, and transparent to the larger quanta of combustion radiation, at the same time the refractories act toward the latter as perfect mirrors, and the cooled-metal surfaces receive the full impact of radiation from the burning fuel.*

These ideas are equivalent to the conception that the first atomic layer on the water-cooled metal surfaces has the furnace-gas temperature, while the next layer of the same thickness of one atom has the temperature defined by the rate of heat conductance. Thus one understands easier the selective partial absorption of the larger combustion quanta by the water-cooled metallic surface. The sharp drop of temperature from the exposed atomic layer to the next layer of the same thickness, of one atom, is explainable by the theories of electronic excitation. It is, however, necessary to note that the first atomic layer is maintained at furnace temperature not because of absorption of the gaseous radiation but because of reradiation of the unabsorbed fractions of the combustion quanta, and the furnace-gas heat content is the consequence of this reradiation. Thus from an engineer's standpoint the path of heat energy is as follows:

The combustion quanta leave the burning molecules, reverberate in the furnace being reflected by the molecules of gas excited to the furnace temperature level, find the cooled metallic surfaces, enter the first atomic layer and are partially absorbed, the unabsorbed fractions being reradiated back into the furnace gas whose excitation level permits their absorption by still lesser fractions and after many reverberations. The lesser furnace-gas quanta cannot be absorbed by the water-cooled walls because the first atomic layer is excited to the same level, or in other words, it has the furnace-gas temperature, and the process of radiation absorption is a purely selective one during the many million reverberations.

It can now be considered that the radiant-heat absorption by water-cooled surfaces is an energy transfer directly between the combining molecules of the fuel and the water-cooled surfaces, the solid angles, the extent and shape of refractories, and the composition of furnace gas having nothing to do with it. Only the degree of decomposition of $2CO_2$ into 2CO and O_2 has an influence on the values of combustion quanta. It is obvious also that the heat transfer by convection on surfaces exposed to radiation of combustion is zero. Thus a sharp distinction is drawn between the radiation from the combining molecules, and the general residual radiation. It is quite unfortunate that the majority of radiation estimates based on the Stefan-Boltzmann law take this residual radiant energy, better to say "radiant-exhaust" energy, as the initial state or the "radiant-inlet energy."

Many experiments and models on gas flow in banks of tubes show a clear streamline-velocity field somewhat distorted by local turbulence, and superimposed on the unseen molecular-velocity field. In the presence of a heat-absorbing surface the flow is distorted by friction, and a violent turbulence is generated in the "gas film," gradually subsiding toward the undisturbed flow. A simple rough calculation would show that if the gas in the film

moves relatively to the absorbing surface with one-half of the velocity, still the amount of heat passing by in the film is sufficient to account for the known values of heat transfer by convection at the thicknesses of the film less than $^1/_8$ in., if the rate of heat exchange between the film and the metal is comparable to that by radiation. *Hence the major difference between the heat transfer by radiation and by convection from the standpoint of energetics is in the carriers. In radiation the carriers are the combustion quanta whose number is equal to the number of combining molecules while in convection the carriers are the molecules of gas whose number is in a definite ratio to the combining molecules.* The minor difference will be considered in the derivation of formulas.

Thus in making a comparison between the two phenomena of heat transfer it is seen that the process of combustion in radiation is equivalent in the convection to the diffusion of heat into the gas film, and the turbulent mixing with the fresh gas from the main flow. In order that the same type of relationship holds in both cases it must be assumed that the possible rate of heat exchange between the film and the main flow is greater than the heat exchange between the film and the metal. This assumption can be substantiated by estimating the ratio between the number of gas molecules in contact with the surface of metal and the number of molecules of gas in the gas layer having the thickness of the mean free path of the molecule.

From the viewpoint of energetics, all the forms of energy are subject to the same laws of transformation or exchange, and hence, the heat transfer can be compared with the most convenient of the well-known processes. The peculiarity of radiation

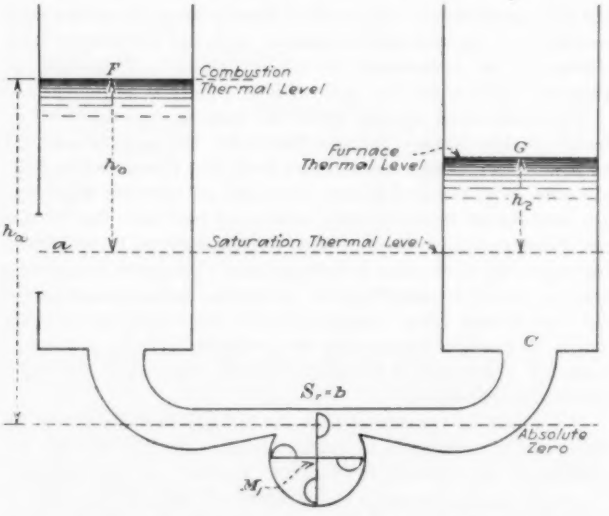

FIG. 1 HYDRODYNAMIC ANALOGY MODEL FOR RADIATION

is in the independency of the rate upon the "back pressure," the rate of radiation is a function of the absolute temperature. In hydrodynamics there is the same condition for the gas flow when the velocity is above the critical value, hence the most convenient form of analogy will be the hydrodynamic one. Thus to this apparent break in the continuity of heat-energy exchange process may be fitted the break in the hydrodynamic energy transformation occurring at critical velocities.

Appendix 2—Hydrodynamic Analogy

Fig. 1 shows the model for radiation, Fig. 2 is for convection. The turbine wheels between the two capacities represent the first atomic layer of the water-cooled metallic surface which absorbs the heat.

The combustion of q lb. of fuel per second, which evolves the flow of G lb. of gas per second, corresponds to the inlet of Q lb. per sec. of a fluid in the models. $Q = gG$ where g is acceleration of gravity. Further the fluid pressures or heads h will be set proportional to heat contents in one pound of gas H in such a way that $Qh = JGH$ where J is the mechanical equivalent of heat. In these conditions the work produced by the turbine wheels M_1 and M_2 of the two models will correspond to heat transmitted to water. The radiation model (Fig. 1) has the combustion

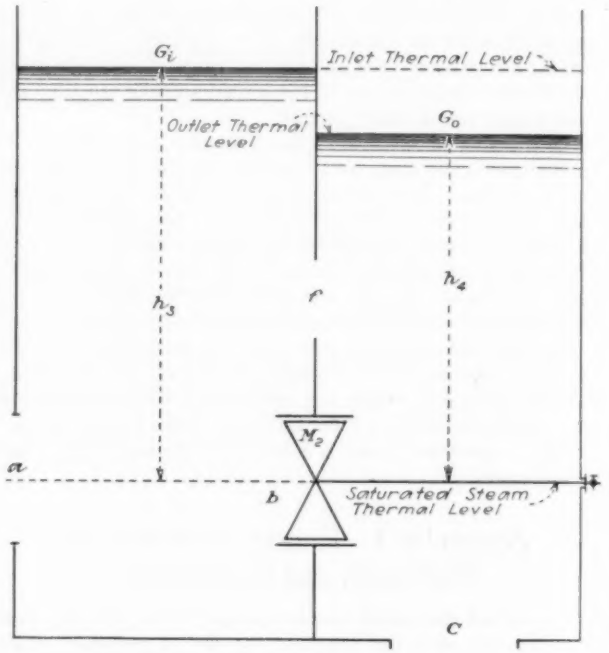

FIG. 2 MODEL FOR CONVECTION

orifice a, the area of which is proportional to the number of combining molecules or to the rate of firing. The turbine nozzle b is of constant area = S_r = heating surface (projected) exposed to radiation, C is the outlet orifice into the convection zones. The combustion of q lb. of fuel per sec. is equivalent to the inlet of Q lb. per sec. of the fluid in the reservoir F against the head h_o, which is the flame, and the total head in this reservoir is h_{oo}, corresponding to the total heat content in one pound of the gas above the absolute-zero temperature. In order to represent the radiation absorption it must be assumed that the turbine M_1 is of the impulse type utilizing the full velocity produced by the absolute head h_{oo} and that the velocity is higher than the critical value for the fluid, and hence independent of the back pressure. This puts the level of the turbine at absolute zero. The reduced velocity of the fluid after leaving the turbine builds up the back pressure by means of the diffuser. The vessel G corresponds to the heat capacity of the gas in the furnace, and the back pressure (h_2 above the saturation level) corresponds to the thermal level in the furnace gas. The head h_o corresponds to the total available sensible heat per pound of gas above the saturation temperature.

In the convection model (Fig. 2) the vessels G_1 and G_0 represent the heat capacities of the gas respectively entering and leaving the convection zone. The orifice a represents the inlet-gas orifice and its area is proportional to the mass flow of gas; the orifice C is for the outlet. The orifice b is constant, and its area is equal to the convection heating surface S_c sq. ft. M_2 is a reaction turbine the work of which is equivalent to the heat

transmitted to water. The phenomenon of convection depends upon the difference of temperatures (heads), and hence a reaction turbine must be assumed in which the velocity of the fluid is below the critical value. The furnace is an almost complete enclosure for the radiation, while in the convection zone the clearances between the tubes across the flow constitute orifices of leakage shown on Fig. 2 by f. For a bank of tubes with parallel flow of gas the enclosure is practically complete. The heads h_3 and h_4 represent the mean heat contents in one pound of gas at the inlet and the outlet, respectively. Thus the whole convection surface of a crossflow boiler of the B. & W. type will be thermally a turbine with as many reaction stages as there are rows of tubes between the baffles of the gas passage, and the radiant surface will be thermally a single-impulse wheel.

Appendix 3—Radiant-Heat-Absorption Formula

Take the bucket efficiency of the impulse wheel = 100 per cent. The power developed by the wheel = $Q\ (h_o - h_2)$.

Denote by μ_1 the fraction of total available heat (above saturation) in one pound of gas H_o absorbed by radiation. Then:

$$J\mu_1 H_o = Q(h_o - h_2)$$

also

$$\mu_1 = \frac{h_o - h_2}{h_o} = \frac{1}{1 + \frac{h_2}{h_o - h_2}} \quad \ldots\ldots\ldots\ldots [6]$$

Consider first the nozzle which is the combustion orifice whose area is proportional to the rate of firing. If the combustion efficiency (degree of dissociation of CO_2) is kept constant the head h_o and the velocity of the jet will be constant. Let us denote for one pound of gas:

$$h_{oo} = h_o + \frac{JC_pT_s}{g} = h_o\ (1 + a)$$

which thermally is equivalent to

$$H_{oo} = H_o + C_pT_s = H_o\ (1 + a)$$

where T_s is the absolute saturation temperature and C_p the mean specific heat of gas between the absolute zero and the saturation temperature.

Let us take now two wheels, identical in design but built on

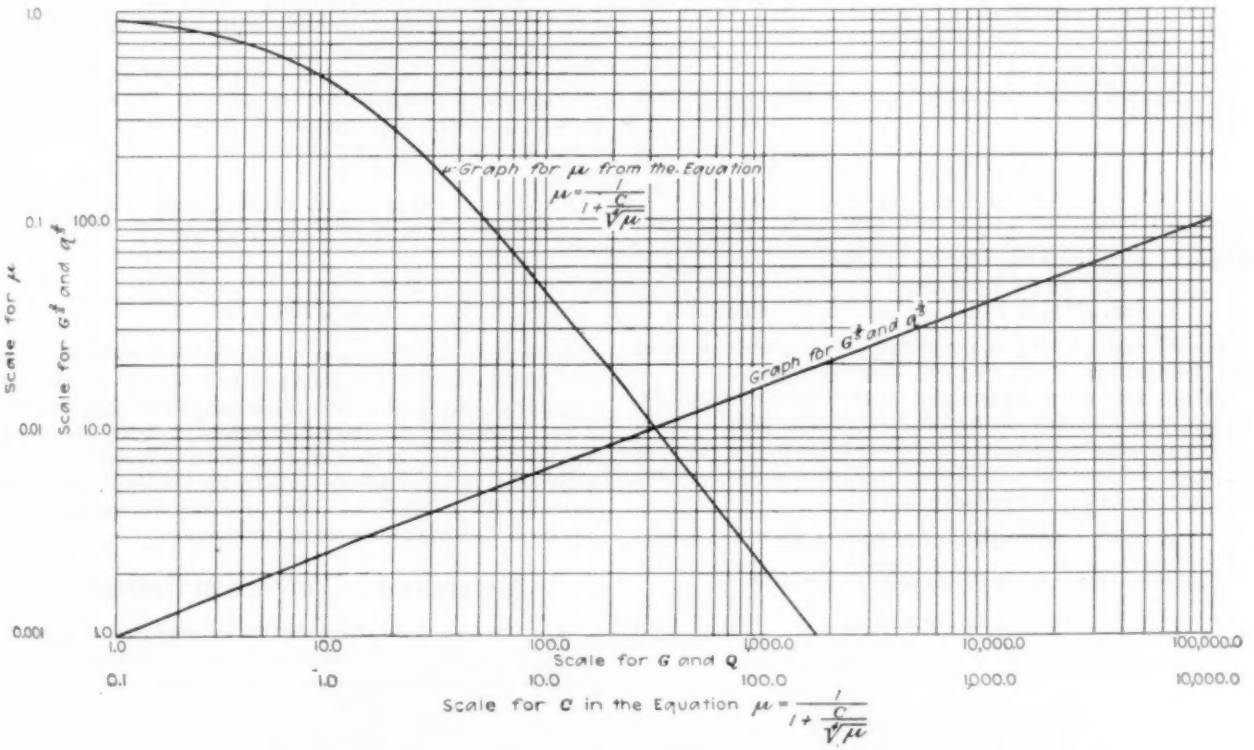

FIG. 3 GRAPHICAL SOLUTIONS OF BOILER AND SUPERHEATER PERFORMANCE

different scales, the relative linear scale being s. Under corresponding hydrodynamic conditions the flows will vary as $s^{5/2}$ or $s = \left(\frac{Q_2}{Q_1}\right)^{2/5}$.

The heads will be of course in the linear ratio s.

Let the first wheel be allowed to run at different speeds when the amount of flow is variable, then at Q discharge, taking the wheel alone:

$$\frac{h_2 + ah_o}{h_o - h_2} = K_1 s = K_2 Q^{2/5} \quad \ldots\ldots\ldots\ldots [7]$$

This will be valid if the speed and the bucket position adjust themselves in such a way that the effective outlet area is increasing in the ratio $s^2 = \left(\frac{Q_2}{Q_1}\right)^{4/5}$. The last requirement corresponds to the requirement of maximum action. If another wheel similar in design but with a larger area of the nozzle S_r be put in the same hydrodynamic conditions, the scale will be reduced by $\sqrt{\frac{S_r}{S_{ro}}}$.

Hence in general

$$\frac{h_2 + ah_o}{h_o - h_2} = K_3 \frac{Q^{2/3}}{\sqrt{S_r}} \quad [8]$$

Combining (8) and (6) we get:

$$\mu_1 = \frac{1 + a}{1 + \frac{K_3 Q^{2/3}}{\sqrt{S_r}}} \quad [9]$$

Substituting the thermal values in [9]

$$\mu_1 = \frac{1 + a}{1 + \frac{K_4 Q^{2/3}}{\sqrt{S_r}}} \quad [10]$$

This formula differs very little from the well-known Orrok formula:

$$\mu_1 = \frac{1}{1 + \frac{A}{27}\sqrt{\frac{C}{S_r}}}$$

where S_r = radiant surface (projected) in sq. ft.
A = lb. of air per lb. of coal
C = lb. of "good bituminous coal" fired per hour.

The difference is only in the exponent for the rate of firing and the results given by both formulas are very close.

Taking Orrok's formula as representing in the closest way the experimental data and choosing the adjustment point at 6 lb. of coal per hour per square foot of projected radiant surface, 15 lb. of air per pound of coal, 200 sq. ft. radiant surface and 390 deg. fahr. saturation temperature, we get

$$K_4 = 35.0 \text{ at } H_o = 710 \text{ B.t.u. per lb.}$$

If the rate of firing is given in pounds fuel per hour:

$$K_4 = 1.32$$

The coal considered here is of the following analysis:

H_2	4.3%
C	78.0%
(S)	0.5%
$N_2 + O_2$	4.8%
Ash	8.0%
Moisture	4.4%
Total	100%

The number of combining molecules per pound is proportional to a sum b:

$$b = \frac{C}{12} + \frac{H_2}{2} + \frac{CO}{28} + \frac{S}{32} + \frac{H_nC_m}{n + 12_m}$$

where the chemical symbols denote respective percentages of these constituents in the fuel analyzed as fired.

For the "good bituminous coal" $b = 8.67$, hence for firing rate q_1 of any other fuel, the q in the radiation formula: $q = fq_1$ where the fuel factor

$$f = \frac{1}{8.67}\left(\frac{C}{12} + \frac{H_2}{2} + \frac{CO}{28} + \frac{S}{32} + \frac{H_nC_m}{n + 12_m}\right)$$

Hence:

$$\mu_1 = \frac{1 + a}{1 + \frac{35\,(fq)^{2/3}}{\sqrt{S_r}}} \quad [11]$$

It is impossible to derive the constant K_4 theoretically, but the upper and lower limits for the constant can be estimated.

The number of iron atoms per square foot of projected cylindrical surface is 2.84×10^{16}. The number of combustible molecules per pound of the "good bituminous coal" is 2.31×10^{22}. The frequency of atomic vibrations for iron is 1×10^{13}. The maximum frequency of radiant energy during combustion of C to CO, V_1, is computed at 7.05×10^{17}. The frequency V_2 corresponding to 2800 deg. K (5040 deg. fahr. abs.) can be computed from the expression:

$$hv_2 = \frac{3}{2}RT$$

where R = gas constant = 1.372×10^{-16} ergs, h = Planck's constant, $V_2 = 8.8 \times 10^{13}$.

The constant K_4 is the relative weight of the units in terms of atomic oscillations and waves of radiation. The upper limit for K_4 is defined by the frequency V_1, while the lower limit will be fixed by the frequency V_2.
Hence:

$$(K_4)_{max} = \frac{(2.31 \times 7.05 \times 10^{22} \times 10^{17})^{2/3}}{(2.84 \times 10^{16} \times 10^{13})^{1/3}} = 72.0$$

$$(K_4)_{min} = \frac{(2.31 \times 8.8 \times 10^{22} \times 10^{13})^{2/3}}{(2.84 \times 10^{16} \times 10^{13})^{1/3}} = 1.98$$

The mean is 37, quite close to the empirical value 35. The value of the constant depends upon the molecular processes of liberating the quanta of radiation about which very little is known so far. The higher frequency V_1 is computed on the assumption that the whole heat of molecular oxidation is radiated without the recoil energy, and this accounts for the too high value which runs up to X-rays, while the lowest frequency corresponds to the position of the maximum in the infra-red region.

Appendix 4—Convection Formula

As in the case of radiation the bucket efficiency is taken as 100 per cent. Let G pounds of gas, each containing H_c B.t.u. available above saturation temperature, enter the convection zone per second.

$$H_o = H_o\,(1 - \mu_1)$$

The thermal equilibrium is attained not instantaneously but in a time somewhat shorter than the time of gas passage through the row of tubes. To account for this we have to change the impulse wheel of the radiation to a reaction wheel shown on Fig. 2. The difference between the reaction and the impulse wheels is in the velocity of the hypothetical fluid passing the wheels. In the case of the impulse wheel the velocity is $V_i = \sqrt{2gh_{oo}}$ (see Fig. 1) which is independent of the rate of firing. For the reaction wheel the velocity will be $V_r = \sqrt{2g(h_o - h_2)}$.

The ratio of velocities $\frac{V_r}{V_i} = \sqrt{\frac{h_0 - h_2}{h_{oo}}} = \sqrt{\frac{\mu_1}{1 + a}}$

Fig. 2 represents the model for convection.
Denoting:

G_i = gas volume inlet
G_o = gas volume outlet
a = gas inlet orifice
c = gas outlet orifice
b = heating surface orifice = S_c sq. ft.
f = "leakage" orifice
M_2 = reaction wheel representing the action of the first atomic layer on S_c

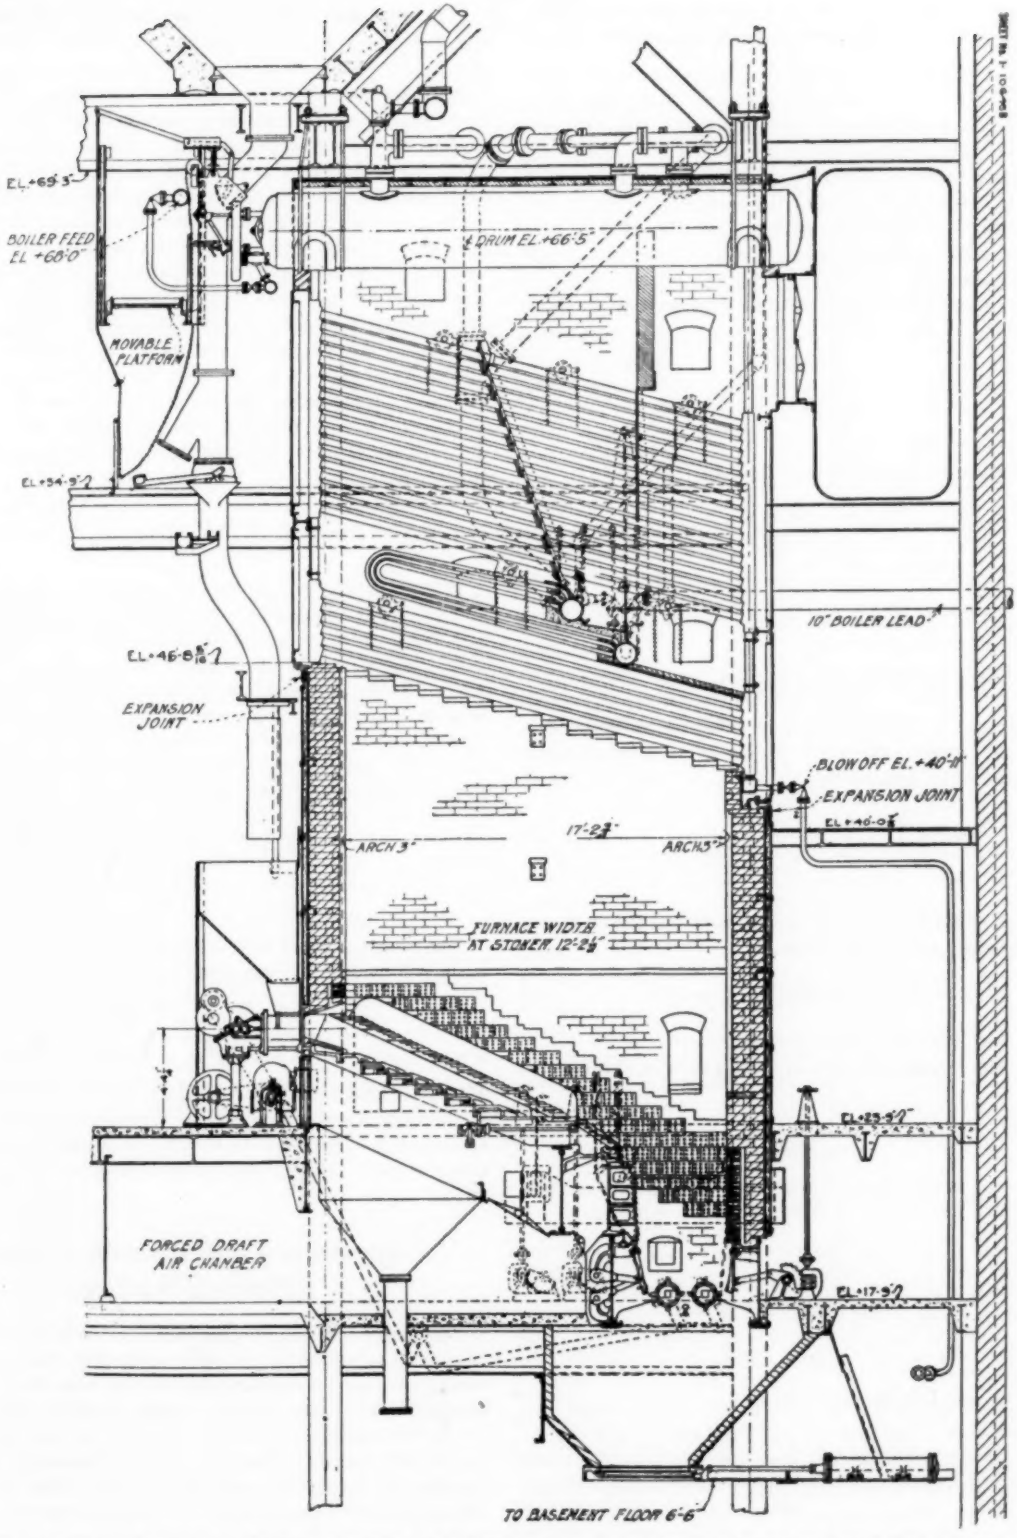

FIG. 4 CROSS-SECTION OF BOILER, STOKER, AND FURNACE AT FIFTY-NINTH STREET POWER HOUSE OF THE INTERBOROUGH RAPID TRANSIT COMPANY

$h_3 = \frac{JH_e}{g}$ = head representing inlet heat content in one pound of gas above saturation temperature, B.t.u. per lb.

h_4 = head representing outlet heat content. The "leakage" orifice is introduced here to account for the incompleteness of the enclosure. In a parallel flow boiler (fire-tube boiler, for instance) the enclosure is practically complete, but in a crossflow boiler the clearance between the tubes into the next stage constitutes the orifice of leakage. If l is the distance between centers of the tubes and d the tube diameter, the enclosure factor

$$e = \frac{l}{l + \frac{l - d}{\pi d}} \quad \ldots\ldots [12]$$

For a case of tubes with extended surface:

$$e = \frac{l}{l + \frac{S_g}{S_c}} \quad \ldots\ldots [13]$$

where S_g is the gas passage area, sq. ft. and S_c is the heating surface. Evidently:

$$S_c\,(1 - e) = f = \text{orifice of leakage}$$

Thus only the fraction e of gas is effective in convection.

Let μ_c be the wheel's efficiency or the fraction of available heat absorbed by the surface S_c.

$$\mu_c = 1 - \frac{h_4}{h_3} = \frac{1}{1 + \frac{h_4}{h_3 - h_4}} \quad \ldots\ldots [14]$$

The amount of fluid passing the wheel is eQ and the work produced by the wheel per pound of flow, h_e:

$$h_e = eh_3\mu_c \text{ or thermally, } H_e = eH\mu_c \quad \ldots\ldots [15]$$

which is the heat available above saturation at the inlet.

Using the same considerations as in the case of the impulse wheel

$$\frac{h_4}{h_3 - h_4} = \frac{K_6\,(eQ)^{2/3}\sqrt[4]{1 + a\frac{h_e}{h_3}}}{\sqrt[4]{\mu_c}\,\sqrt{S_c}} \quad \ldots\ldots [16]$$

or thermally

$$\frac{H - H_e}{H_e} = \frac{K_6\,(eG)^{2/3}\sqrt[4]{1 + a\frac{H_e}{H}}}{\sqrt[4]{\mu_c}\,\sqrt{S_c}} \quad \ldots\ldots [17]$$

connecting [14] and [17] we get:

$$\mu_c = \frac{1}{1 + \frac{C}{\sqrt[4]{\mu_c}}} \quad \ldots\ldots [18]$$

$$C = \frac{K_6\,(eG)^{2/3}\sqrt[4]{1 + a\frac{H_e}{H}}}{\sqrt{S_c}} \quad \ldots\ldots [19]$$

$$H_e = eH\mu_c \quad \ldots\ldots [20]$$

C is calculated directly, μ_c is read from the graph of solutions for [18] given on the diagram of Fig. 3, and then H_e is easily computed. The constant K_6 is intrinsically the same as that for radiation except that the number of molecules per pound of gas is different from the number of combustible molecules per pound of coal, and also the frequency of collisions of gaseous molecules with the wall differs from the radiation frequency. Here the hydrodynamic model helps. At the same amounts and potentials of hydrodynamic energy, the efficiencies of the wheels differ only due to their type. Hence the heating effect by radiation and by convection must be the same per pound of gas with H_e available heat content. For radiation the initial heat content H_e is being produced by combustion of C and H_2 molecules in the coal. For convection the same heat content may be regarded as produced, for instance, by a mechanical agitation of N_2 and O_2 molecules. Hence, on the average, 13 lb. of gas are equivalent to one pound of fuel for which the fuel factor is $100/(30.5 \times 8.67) = 0.378$ where 30.5 is the molecular weight of furnace gas.

$$\text{Thus } K_6 = 35 \times \left(\frac{1}{0.378 \times 13}\right)^{2/3} = 18.5$$

It is gratifying to note that the derivation of the constant for convection is impossible without the hydrodynamic analogy, and the correctness of its value as shown by the checking of actual boiler tests, which support the validity of the considerations. There are some cases (Brown-Boveri boiler) where combustion takes place at a pressure higher than the atmospheric. The frequency of collisions between the molecules of gas and the atoms of metal is proportional to pressure, hence, if p is pressure in pound per square inch, the formula [19]

$$C = \frac{18.5\left(eG\frac{p}{14.7}\right)^{2/3}\sqrt[4]{1 + a\frac{H_e}{H}}}{\sqrt{S_c}} \quad \ldots\ldots [21]$$

The constant $K_6 = 18.5$ depends upon the metal of which the surface is made. If some other metal than iron is used

$$K_6 = 18.5\sqrt{\frac{25}{K}} \times \sqrt[3]{\frac{7.85\omega}{56\delta}} \times \sqrt{\frac{v_i}{v_m}} \quad \ldots\ldots [22]$$

Here K is heat conductance in B.t.u. per hr. per ft. per deg. fahr., δ = density in respect to water, ω = molecular weight, v_i = atomic frequency for iron $= 1 \times 10^{12}$, v_m = atomic frequency of the other metal. Usually this correction of the constant is very slight.

Appendix 5—Refractory-Protected Heating Surfaces

Sometimes the furnace tubes are covered with refractory-lined blocks. Carborundum is used often for this purpose. The main constituent of carborundum is CSi (carbide of silicon). Its density is 3.12, and atomic weight is 40.4. The number of atoms is 2.44×10^{16} or 3.82×10^{16} per sq. ft. of projected cylindrical surface. The frequency of molecular oscillations is close to that of the diamond, 3.0×10^{12}. Thus if the heat conductance of carborundum was the same as that of iron, the constant $K_4 = 35\sqrt{\frac{2.84 \times 10^{28}}{3.82 \times 3.0 \times 10^{28}}} = 17.4$. But the lower degree of conductance reduces the number of effective atoms in the ratio of conductances. For iron the conductance may be taken at 26.0 B.t.u. per hr. per ft. per deg. fahr. For carborundum at high temperature it runs up to 2.5. Hence the constant

$$K_4 = 17.4\sqrt{\frac{26}{2.5}} = 56.$$

Usually the radiant surface is protected by such blocks only partially. Let S_1 be the projected heating surface covered with blocks, and S_2 the projected bare-tube surface. The order of applying the formula is as follows:

(1) The fuel rate for the block-covered surface is reduced to:

$$q_1 = \frac{qS_1}{S_1 + S_2}$$

(2) Fraction of radiant heat absorbed on the block-covered tubes is

$$\mu_1{}^b = \frac{1 + a}{1 + \frac{56\ (fq)^{2/3}}{\sqrt{S_1}}}$$

The residual heat H_c above the saturation is computed.

$$H_c{}^b = (1 - \mu_1{}^b)\ H_1$$

(3) Absorption of the primary radiation on bare tubes is calculated for the full rate of firing q

$$\mu_1 = \frac{1 + a}{1 + \frac{35\ (fq)^{2/3}}{\sqrt{S_2}}}$$

(4) The reduced quanta reradiated from the block-covered surfaces are absorbed on the bare surface, the latter dealing with the total number of quanta, proportional to q. Hence the total heat absorptions A in B.t.u. per hour are:

For the block-covered surface, $A_1 = \frac{GS_1}{S_1 + S_2} \times \mu_1{}^b H_e$

For the bare surface, $A_2 = \left(H_e + \frac{S_1}{S_1 + S_2} H_c{}^b\right) \mu_1 G$

Thus covering by blocks of a part of heating surface results in a somewhat increased thermal load on the unprotected bare tubes

So far the rate of heat absorption on the block-covered tubes is independent of the thickness of the refractory lining. The greater the thickness the higher the temperature of the second atomic layer in the refractory, and when it reaches the furnace-gas temperature or that of the first atomic layer, the rate of heat absorption remains constant (independent of the rate of firing). This limit can be found by a trial and error method.

The furnace temperature t_f in degree fahrenheit is

$$t_f = \frac{GH_e - (A_1 + A_2)}{C_p G} + (T_s - 460)$$

where C_p is the specific heat of furnace gas, it may run up to 0.28, and T_s = saturation temperature, deg. fahr. abs.

Appendix 6—Test Results at Interborough Rapid Transit Company

In a paper presented before the A.S.M.E. in 1926, H. B. Reynolds, J. M. Taggart, and R. S. Lane give results of tests on a Babcock & Wilcox boiler at the Fifty-ninth Street Station of the Interborough Rapid Transit Company, New York City. Fig. 4 shows the boiler. It is 24 tubes high and 21 tubes wide with a heating surface of 11,400 sq. ft. (10,560 sq. ft. in tubes), and superheating surface of 1485 sq. ft. Of the latter about 90 per cent is effective.

Distribution of Heating Surface

1 Projected surface exposed to radiation = 259 sq. ft.

2 First convection zone, 6 rows of 440 sq. ft. $5\frac{1}{2}$ rows are effective.

3 Superheater, 6 rows of 222 sq. ft. Total gas passage into second bank, across the superheater, is 58 sq. ft., of which 35.6 sq. ft. is between superheater tubes; hence the superheater utilizes only 61.5 per cent of gas.

4 First pass second bank, 9 rows of 220 sq. ft. and 9 rows of 200 sq. ft.

5 Approximately 40 per cent of gas sweeps the bottoms of boiler drums. Heating surface = 242 sq. ft. Enclosure factor = 0.5.

6 Second pass, 14 rows of 128.5 sq. ft.

7 Parallel flow part between the second and third passes, 792 sq. ft.

8 Third pass, 14 rows of 106 sq. ft. and one row of header nipples.

In calculations the soot correction was taken as 20 per cent reduction of tube surface which is equivalent to a rise in constant's value to 23.1. For the superheater tubes the reduction was taken 15 per cent, due to smaller diameter of tubes. Throughout the boiler surface the corrected enclosure factor was 0.770 and for superheater 0.842. Tests 7, 9, and 15 were selected as giving the lowest unaccounted-for losses.

The result of the calculation is as shown in Table 1.

The graph of the test gives a constant superheat of 200 deg. fahr. The gas readings for tests 7 and 15 are somewhat off,

TABLE 1

Radiation absorption, μ	0.332	....	0.297	....	0.255	....

and hence the calculated values which depend upon the gas flow.

The flue-gas temperature readings are always lower than the calculated values; this may be attributed to air leakage. Of course the temperature of steam depends upon the moisture in saturated steam; test results do not contain moisture data and it was assumed 0.5, 1.0, and 1.0 per cent, respectively. In the case of the low rating in test 7 it is quite possible that the resistance to gas flow through the first bank was insignificant, and hence more than 61.5 per cent of gas passed the superheater, according to the natural direction of the flow. (See Fig. 4.) This will make up the shortage of calculated superheat at test 7.

Appendix 7—Test Results at Detroit Edison Company

In a paper presented before the A.S.M.E. in December, 1922, Paul W. Thompson gives results of tests on a 2365-hp. Stirling "W" boiler at Connors Creek Station of the Detroit Edison Company. Beside having the flow of gas mostly parallel to the tubes, this boiler is interesting because it was tested with two sets of baffling. (Figs. 5 and 6.)

The present method must be able to show the effect of change in baffling and consequently three tests were checked for each system of baffling.

The calculations were made in the following way for tests 43, 40, 42, 64, 63, and 66.

Distribution of Heat Absorbing Surface. Baffling "A."

(*a*) Projected surface exposed to radiation = 1165 sq. ft. For one side:

(*b*) First bank in the furnace minus surface exposed to radiation = 3800 sq. ft. It was assumed that 5, 10, and 15 per cent

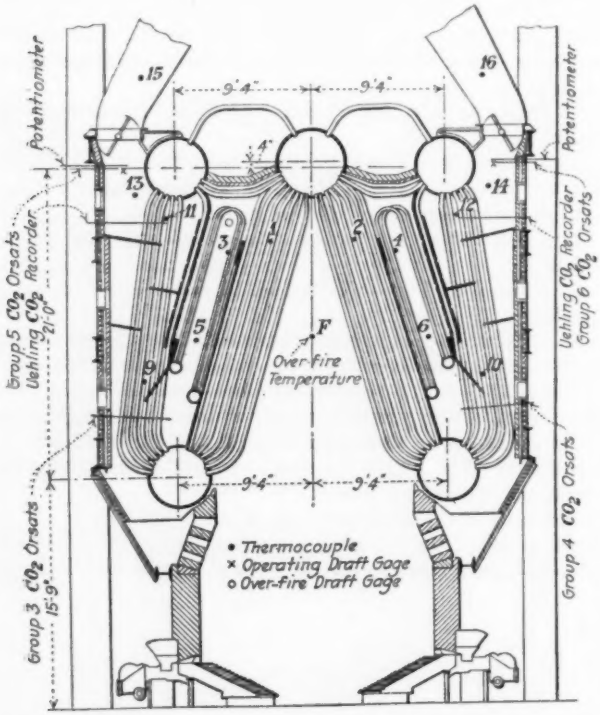

FIG. 5 BAFFLE ARRANGEMENT "A" OF DETROIT EDISON COMPANY BOILER

of gas penetrates in this bank on each side of the boiler on tests 43, 40, and 42, respectively.

(*c*) First pass: Crossflow consists of seven rows of 286 sq. ft. each. Six rows of 250 sq. ft. are effective, one row being fully loaded with radiation.

(*d*) Second pass: The circulating tubes (430 sq. ft.) are neglected due to the dead pocket produced by draft. The superheater (1495 sq. ft.) is divided into two stages: 350 sq. ft. first stage, crossflow, and 1145 sq. ft. second stage, parallel flow.

(*e*) Third pass. Inlet: 5 effective rows of 147 sq. ft. each, crossflow, then 3157 sq. ft. with parallel flow, and finally 5 rows of 123 sq. ft. each as crossflow outlet.

Baffling "B."

(*a*) Projected surface exposed to radiation same as "A" 1165 sq. ft.

(*b*) The convection on two rows exposed to furnace gas was neglected because the surface is loaded with radiation.

(*c*) First pass: 7 rows of 136 sq. ft. each; 6 rows of 85 sq. ft. were taken as effective.

(*d*) Second pass: The return tubes were neglected and the superheater was considered in two crossflow stages of 250 sq. ft. and 1245 sq. ft. The first bank of tubes in the second pass was taken in three stages. Two rows of 520 sq. ft. crossflow, 2340 sq. ft. parallel flow; two rows of 260 sq. ft. crossflow outlet.

(*e*) The third pass was not changed. Same as for baffling "A."

The heat absorption per pound of gas was calculated in every one of the mentioned stages. The steam temperature was calculated by using the ratio of superheater to boiler absorption, neglecting the effect of moisture in saturated steam, which is very small in such boilers, at moderate ratings. (See Table 2.)

Actual flue gas was cooled by air leakage, and moreover the

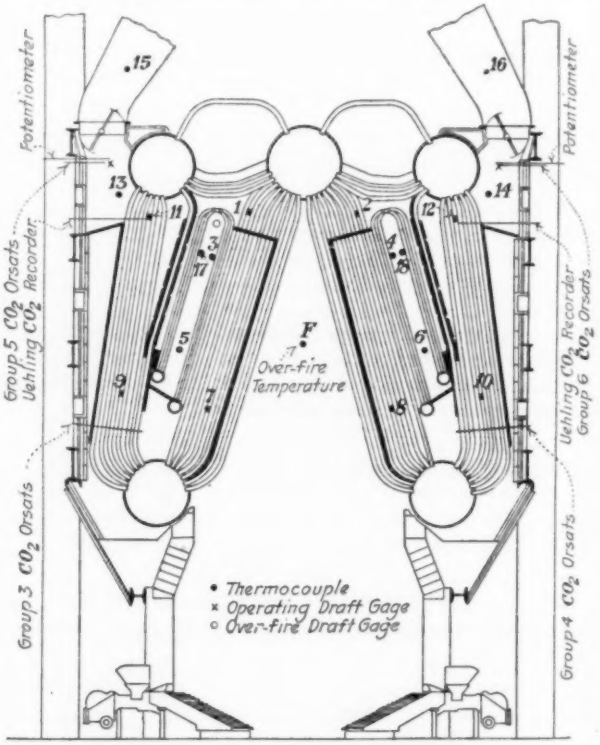

FIG. 6 BAFFLE ARRANGEMENT "B" OF DETROIT EDISON COMPANY BOILER

downcoming water in the third pass was cooler than the saturated steam due to relatively cold feed. The over-fire temperatures are doubtful figures and are given here to show the order of differences. The high calculated superheat at both high ratings is due to the neglect of moisture effect. The data of the test do not contain moisture determinations. The gas readings during these tests were better for the 64, 63, and 66 tests, and hence there is better agreement in general between the calculated and observed values.

Appendix 8—Tests on a Scotch Marine Boiler

The Bureau of Mines Bulletin No. 214 contains results of tests made on a Scotch marine boiler by John Blizard, A. R. Mumford, and R. A. Sherman. The boiler was tested on coal and oil,

and being also of entirely different type from those discussed, it presents unusual interest for checking the hydrodynamic similitude method.

The heating surface is distributed as follows:

(1) Furnaces and combustion chambers 702 sq. ft. when fired with coal and 947 sq. ft. when fired with oil.

(2) Inner surface of the fire tubes = 2075 sq. ft. to which must be added 1300 sq. ft. of retarders, except test 13 which was run without retarders.

From the multitude of tests analysis will be made of 13, and 12 with coal firing and 26, 50, and 33 with oil firing.

The calculations were made in the following way: Radiant surface was taken as that of furnaces and combustion chambers. The inner surface of the fire tube was taken as convection zone. Due to difference in power in which G and S enter into convection formula, the tubes were taken individually, which makes a considerable difference. Furthermore, the flow of gas referred to convection surface is very low in this case, and the streamline velocity field cannot be maintained, hence a general turbulent flow must be assumed.

Any tube may be divided into any number of sections in series, which will, of course, give different rates of absorption, increasing with the number of stages. For the condition of maximum action the number of stages must be also a maximum and the shortest section must be determined where the conditions of flow approach the forced streamline field. Considering the rolling of gas in the tube, the least length ought to be $\pi d/2$, where d is inner diameter. Actual dimensions of tubes in the boiler require accordingly 28 sections or stages.

The results of calculations and the observed values are given in Table 3.

Appendix 9—Further Analysis of the Heat-Absorption Formulas

The fraction of heat content in one pound of gas absorbed as radiation is

$$\mu_1 = \frac{1 + a}{1 + \frac{35\,(fq)^{2/3}}{\sqrt{S_r}}}$$

Let us reduce q to a very small amount $q \approx 0$ (a candle for instance) leaving $G \approx 0$. This would mean practically a circulation of hot gas through the furnace. In these conditions the formula indicates $\mu_1 = 1 + a$. This is impossible because it means cooling of the gas to the absolute zero temperature. Hydrodynamically (Fig. 1), these conditions are equivalent to a flow against the head. From this it is seen that there exists a certain limit to the application of the radiation formula. In order that the heat is carried from the burning fuel to the water by radiation the outlet velocity head from the impulse wheel on the hydrodynamic model must be sufficient to counterbalance the head of saturation level. This critical velocity head or a critical minimum rate of combustion will define also the maximum value of μ. From Fig. 1 it is seen that $\mu_{max} = \frac{h_o}{h_{oo}} = \frac{1}{1 + a}$, hence the critical rate of combustion may be calculated from the expression:

$$\frac{1}{1 + a} = \frac{1 + a}{1 + \frac{35\,(fq)^{2/3}}{\sqrt{S_r}}}$$

When the rate of combustion is below the critical value then for calculating heat absorption in the furnace instead of the radiation formula it is necessary to use the convection formula:

$$\mu_1 = \frac{1}{1 + \frac{18.5\,G^{2/3}\,4}{\sqrt{S_r}}\sqrt{\frac{1 + a}{\mu_1}}}$$

which is suitably re-written for the case. This critical rate of combustion is low. For instance, in a 1500-hp. boiler S_r = 900 sq. ft., H_o = 1000 B.t.u. per lb., T_s = 460 + 440 = 900 deg. fahr., f = 1.0, $a = \frac{0.22 \times 900}{1000} = 0.198$ and q critical = 0.088 pounds of coal per second or 315 pounds per hour.

The wide range of the radiation formula can be substantiated in the conditions of the other extreme. With a cylinder of a Diesel engine, at 24 in. diameter the mean surface exposed to radiation during the combustion will be about 7.5 sq. ft. The power developed in one chamber is 650 hp. at 0.45 lb. of oil per hr. The nominal combustion rate is $\frac{0.45 \times 650}{3600} = 0.0813$ lb. per sec. Fuel factor f = 1.4. Actual combustion takes place at 10 per cent of the stroke, or on 37 deg. turn, hence the equivalent rate of coal combustion is $\frac{0.0813 \times 1.4 \times 360}{37} = 1.11$ lb. per sec. Taking the jacket water at 200 deg. fahr. = 660 deg. abs. and H_o = 1200 B.t.u. per lb.: $a = \frac{0.22 \times 660}{1200} = 0.121$. The fraction of generated heat absorbed as radiation

$$\mu_1 = \frac{1.121}{1 + \frac{35 \times 1.11^{7/8}}{\sqrt{7.5}}} = 0.0782 \text{ or } 7.8 \text{ per cent.}$$

The figure is well within the reasonable limits of jacket loss, leaving a large margin for convection during the remainder of the power stroke. In the convection zones of a boiler, the radiation from hot CO_2, CO, H_2O gas plays a considerable part in the total heat transfer. In the convection formula the decrease in the rate of heat transfer when the gas cools down is reflected by the factor $\sqrt[4]{1 + \frac{aH_o}{H}}$ in the denominator term. The value of it increases as H, the current heat content, is reduced. In actual boilers the value of heat transfer coefficient in the first pass is about 50–70 per cent higher than in the last pass. Take, for example, a row of tubes of 225 sq. ft. total heating surface in the first pass and in the last pass, 50 lb. of gas per second, enclosure factor $e = 0.8$, $a = 0.2$, $H_o = 1200$, $H = 700$ in the first pass, $H = 50$ in the last pass above saturation level. Using convection formulas [2], [3], [4], and the graph, we get in the first pass $\mu_c = 0.086$ and in the last pass $\mu_c = 0.056$; the difference is 54 per cent.

The velocity of gas in boilers runs from 10 to 50 ft. per sec. between the tubes. The overall heat transfer is usually considered as proportional to velocity in power between 0.5–0.8. However, these experimental values are for relatively low velocities.

By equating the heating effect estimates of the two kinds, $G\mu_c = KG^x$, it is seen how the exponent x changes if the coefficient K is a constant. The same row of tubes is taken, 225 sq. ft. with 75 sq. ft. area of gas passage. At a value 40 cu. ft. per lb. for specific volume of the gas, the order of velocity at 15 lb. per sec. is 8.6 ft. per sec. and at 150 lb. per sec. it is 86 ft. per sec.

At $a = 0.2$, $e = 0.8$, the convection formulas and the graph give for $G = 15$, $\mu_c = 0.135$; for $G = 150$, $\mu_c = 0.044$.

If, at $G = 15$, $x = 0.6$, then $K = 0.399$, and for $G = 150$, the exponent $x = 0.561$. If we set, on the other hand, the exponent as constant with the value $= 0.5$, the coefficient K will vary from 0.523 to 0.540, respectively, or an exponential formula would differ from the hydrodynamical model's about 3 per cent in the range

FSP-51-38

A Machine for Making Creep Tests at High Temperatures

By GLEN D. BAGLEY,[1] LONG ISLAND CITY, N. Y.

The demand for materials suitable for operation under stress at high temperatures has made it necessary to investigate the properties of various alloys with regard to their resistance to creep. Various types of machines have been developed for this purpose. This paper describes the apparatus developed by the Union Carbide and Carbon Research Laboratories. Its principal features are a compound lever system of applying the load, similar to that used in regular tensile machines, and a simplified method of measuring the extension of the specimens. The compound lever system makes it possible to determine the load accurately and to use standard 0.505-in. diameter specimens without employing excessive weights, even at relatively low temperatures. The system used for measuring extension is such that the construction of the machine is simplified and the convenience of operation improved. The accuracy is ample for all creep tests except those in which extremely small creeps over long periods of time must be measured.

THE industrial development of many processes has led to the use of higher and higher temperatures, so that the limitation of the process has been found in the properties of

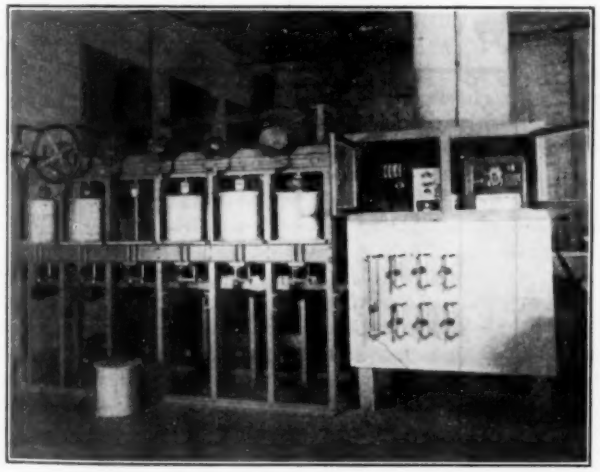

FIG. 1 FRONT VIEW OF THE COMPLETE MACHINE

available materials. Notable improvements in efficiency and capacity might be effected if better materials could be obtained. The governing property in most cases is the slow extension or creep which sometimes occurs at remarkably low stresses when the period of application is long. The only method at present available for determining the value of a given material in this respect is to make long-time tensile tests at elevated temperatures.

The machine described in this paper was developed at the Union Carbide and Carbon Research Laboratories for the purpose of conveniently carrying out a program of such high-temperature creep tests, in connection with the Joint Research Committee on Effect of Temperature on Properties of Metals, sponsored by the American Society for Testing Materials and The American Society of Mechanical Engineers. Since these tests require so long a time, it is essential that the machine give accurately reproducible testing conditions and that it be convenient to operate.

The primary conditions which the machine was to meet were decided upon as follows:

1 To apply a load of 75,000 lb. per sq. in. to a specimen 0.505 in. in diameter
2 To maintain a uniform temperature over the length of the reduced section of the test piece within plus or minus 2 deg. cent. for any desired length of time
3 To measure the creep of the specimen without applying measuring devices to the part of the specimen inside of the furnace.

The appearance of the machine which was developed is shown in the photographs Figs. 1, 2, and 3 and the cross-sectional drawing Fig. 4.

A system of weights which apply tension to the specimen

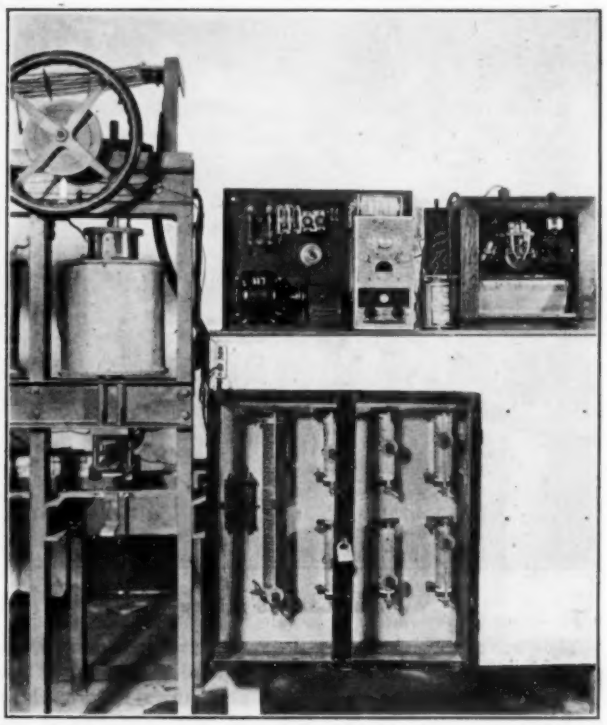

FIG. 2 TEMPERATURE-CONTROLLING MECHANISM AND TEMPERATURE RECORDER

through a compound lever operating on knife edges was chosen for loading. This arrangement has the advantage of a minimum amount of friction combined with compact size and convenient

---

[1] Research Engineer, Union Carbide and Carbon Research Laboratories. Assoc-Mem. A.S.M.E.

Contributed by the Joint Research Committee on Effect of Temperature on Properties of Metals and presented at the Rochester Meeting, Rochester, N. Y., May 13 to 16, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

operation. In order to produce a stress of 75,000 lb. per sq. in. in the 0.505-in. diameter specimen, a total load of 15,000 lb. is required at the specimen. This is obtained with the compound lever as shown, which has a total multiplying effect of one hundred, by applying weights amounting to 150 lb. This weight is low enough to be conveniently adjustable, and yet the ratios of the individual levers are only ten to one, which makes it quite easy to adjust them accurately. For convenience the levers were constructed with two of the knife edges attached to one side and one to the other, and it is therefore necessary to maintain them quite close to the horizontal position. The travel of the weights was limited so that the levers could only turn through a small angle, and in addition a small level was attached to the top of the primary lever to indicate when it was accurately horizontal. An electrical contact was also attached to this primary lever so that by moving the upper head of the machine through the hand wheel, worm and worm gear, and screw, the lever could be adjusted from the front of the machine by observing a small indicating light connected in series with the electrical contact. A swivel joint moving in the plane of the framework on the machine was provided at the bottom of the specimen, and a universal joint allowing motion in all directions was attached between the top of the specimen and the adjusting screw. This universal joint was found necessary to insure accurate axial loading of the specimen. This system provides a satisfactory means of applying loads up to 75,000 lb. per sq. in. to the specimens, although this maximum load is required only at relatively low temperatures. For higher-temperature tests the primary lever is used alone, with the weights suspended directly from it. In this case a correction is made for the loading effect of the secondary lever.

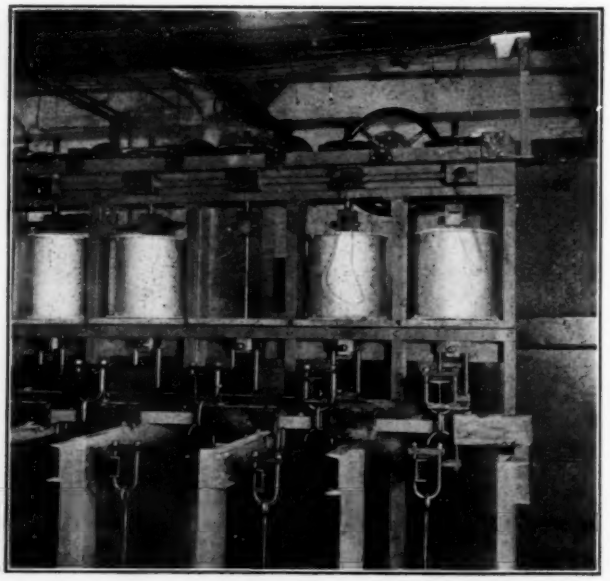

FIG. 3 LOADING SYSTEM

The furnace for maintaining the specimen at the desired temperature is constructed of an alundum tube slightly larger than the specimen; this is fastened inside of a cylindrical sheet-steel case with asbestos-board heads. Sil-O-Cel heat insulation is used between the alundum tube and the furnace shell. The furnace is attached to the upper universal joint so that it moves with the upper end of the specimen, maintaining a tight contact so that there will be no circulation of air through the furnace and past the specimen. This is quite important, as a construction which would allow relative motion between the furnace and specimen would be likely to produce variations in the temperature of the specimen. A Wilson-Maeulen temperature controller was chosen to maintain the temperature constant. A single controlling couple of chromel-alumel wire is used to control the temperature on one furnace. The controller turns the power off and on for all six of the furnaces, according to the temperature of this couple. The temperatures of the other five furnaces are adjusted to be equal to that of the master furnace by series resistances. A Leeds

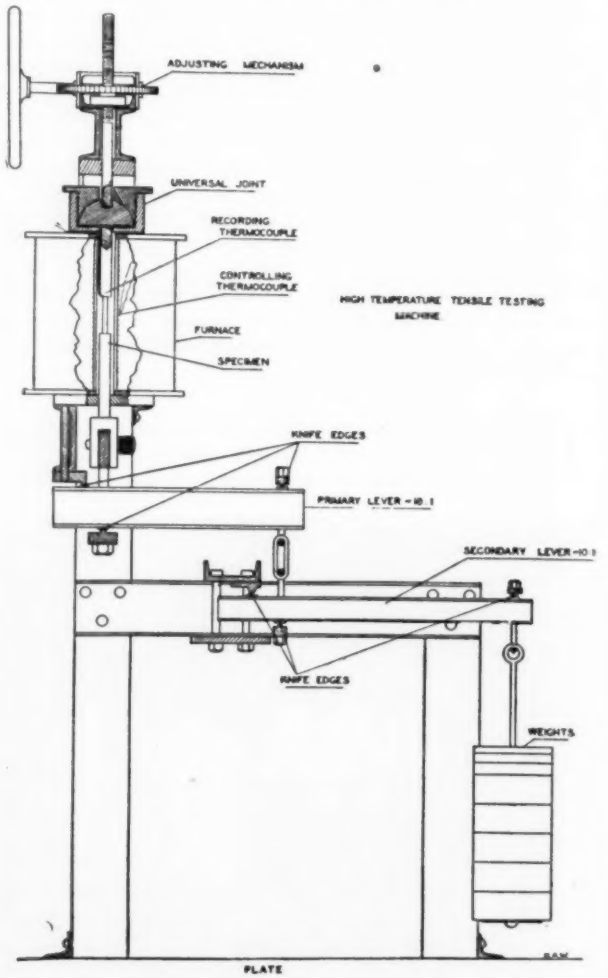

FIG. 4 SECTION THROUGH ONE OF THE ELEMENTS OF THE MACHINE WITH THE FURNACE BROKEN AWAY TO SHOW THE SPECIMEN

& Northrup six-point temperature recorder makes a record of the temperature in each furnace from a recording couple which is inserted in a small hole in the upper shoulder of each specimen. The series resistances are varied until the recorder shows the temperatures of all six of the furnaces to be equal. The controlling couple is not attached to the specimen, but is placed on the outside of the furnace tube in close contact with the winding, from which it is separated by a thin layer of alundum cement. The temperature calibrations on the dial of the controller are entirely disregarded and it is merely set to give the desired temperature at the specimen, the temperature of the winding being from 100 to 200 deg. cent. higher than that of the specimen. If the controlling couple is attached directly to the specimen, a wavy temperature line is produced on the recorder due to the time lag in the transmission of the heat from the winding through the alundum tube to the specimen. With the controlling couple attached

directly to the winding this variation is entirely eliminated, since the temperature of the winding itself is maintained accurately constant. The winding on the furnace is spaced with the turns farther apart at the center of the furnace than at the ends to compensate for the heat conduction through the ends of the specimen. By experimenting with various spacings, an arrangement was found which gave a sufficiently uniform temperature over the length of the reduced section of the specimen.

Methods of measuring the small amounts of creep which occur in tests of this kind offer the most difficulty in operation. The attachment of any form of extensometer directly to the specimen necessitates a less satisfactory form of furnace construction and carries possibilities of changes in the measuring instrument itself due to long-continued operation at high temperature. Optical methods also necessitate special furnace construction which is likely to produce non-uniformity of temperature and involve difficulties in distinguishing the marks on the specimen at high temperatures, especially in cases where considerable oxidation occurs. The method adopted in this machine was to make the large part of the specimen of sufficient section so that its elastic limit could not be exceeded with the load which the reduced section could support. This made it certain that all of the creep would take place in the reduced section of the specimen, and it could then be measured by the motion of the upper head of the machine, since the loading lever is maintained horizontal. The vertical shaft which is connected to the upper half of the universal joint is supported from the top of the machine by a threaded nut which rests on a thrust bearing. This nut is turned by a worm wheel attached to it, which in turn is rotated by a worm attached to a shaft carrying a hand wheel. A calibrated dial is also attached to this shaft and arranged so that the movement of the upper head of the machine is indicated in ten-thousandths of an inch. The furnace is adjusted to a constant temperature, a load applied, and the lever leveled. A zero reading is then taken on the dial and any creep occurring in the specimen is indicated by the movement required on this dial to bring the lever back to the level position. This method has been checked several times and has been found to be sufficiently accurate for any test where creeps of less than one ten-thousandth of an inch in 2 in. are not important.

This machine has given satisfactory results for the purposes for which it was designed, and this description is submitted in the hope that it may prove useful to others who are facing similar problems and promote suggestions and criticisms which will assist in the development of this type of testing with consequent improvement of materials for high-temperature purposes.

Discussion

J. J. KANTER.[2] The construction of creep-testing machines, as well as conducting the tests over extended periods of time, presents many difficulties which any plan of attack may not completely solve. While the equipment in question embodies a number of excellent and original features, it would appear that possibly more emphasis should be placed on certain of the vital refinements to creep testing.

The heart and soul, so to speak, of accurate and dependable creep-testing apparatus is the temperature regulation and control. In order to conduct tests with the highest degree of accuracy and efficiency each unit should be entirely independent of the others for its temperature control. Although a number of investigators consider the using of one temperature controller for several tests a feasible plan, the failure of the single controller to function naturally jeopardizes all of the tests operating in the units. It is extremely difficult to keep a temperature controller in continuous operation without the danger that at some time when no one is present to attend it something will go wrong—motor stopping, breaking of galvanometer suspension, contactor failure, control-thermocouple failure, or even the master furnace burning out. When using an individual controller for each unit, if any of the failures occur but one test is affected.

Another difficulty of maintaining constant temperature in a battery of units using but one controller would seem to arise when discontinuing a test in the master furnace. Control would necessarily have to be established through a second furnace, necessitating a certain amount of rheostat adjustment to maintain within ± 2 deg. cent. of the desired temperatures. It would be of interest to hear more about the adjusting of the series rheostats required in conducting tests with this arrangement.

In regard to creep measurement, the author suggests that extensometer and optical methods give rise to objectionable furnace-design features. While this is true to a certain extent, careful survey has shown that, with the furnace construction necessitated, simultaneous temperature variation over the reduced section of the test piece need not be more than ± 5 deg. cent. total variation.

Presuming that the author has carefully surveyed his furnaces for temperature uniformity over a reduced section of the test specimen by means of calibration test bars, it would be of interest to know what the variations, if any, amount to at the various testing temperatures.

The optical method of creep measurement is objected to on the ground that difficulty is experienced in distinguishing specimen marks, particularly at high temperature. While this is quite true when features upon the specimen itself are used as gage marks, platinum targets suitably attached serve the purpose quite satisfactorily even at temperatures as high as 1400 deg. fahr. and in the presence of heavy scaling.

The leveling of levers as a precision means of determining creep, it seems, would be open to some of the same objections as an extensometer for high-temperature testing—chiefly that external variations in temperature cause change in relative positions of the parts. Discussion of the effects of such variation upon reproducibility of readings and also the torque transmitted to the test piece through the thrust bearing should not be overlooked.

E. R. FISH.[3] With the increase in boiler pressures and size of units, coupled with great improvements in the fuel-burning apparatus, boiler manufacturers are faced with new problems.

Improvements in burning fuel have resulted in much higher gas temperatures. Higher steam pressure means higher steam temperatures and much greater metal thicknesses of the pressure parts. The increased dimensions of boilers involve stresses of considerable magnitude other than those due strictly to the pressure. As there are important changes in the physical characteristics in the materials used in boiler construction beginning at 650 or 700 deg. fahr., and as all the factors mentioned accumulate so as to make somewhat uncertain the actual stresses to be provided for, it is highly important that the behavior of the materials be thoroughly understood.

Among the several phenomena is the so-called creep effect which takes place, the magnitude of which varies with the loading and temperature. It is important that boiler designers have definite and reliable information on this. Not only are comparative figures for varying temperatures and loads useful, but the absolute quantities which can be used in making calculations also are needed. The development of testing machines which give accurate results is one of the important phases of the accumulation of the needed data.

Evolution of the Slag-Tap Furnace at the Charles R. Huntley Station of the Buffalo General Electric Co.

By H. M. CUSHING,[1] BUFFALO, N. Y.

The handling of low-fusion-ash coals at high ratings and with high efficiencies is one of the stiffest problems ever presented to a furnace designer. This paper tells how in their attempt to design a furnace that would burn any coal offered on the Buffalo market the engineers developed the slag-tap furnace for burning powdered coal, after ten years' experience in driving stoker-fired boilers at 300 to 400 per cent of rating. Because of the greater freedom in selecting coals for a powdered-coal-fired furnace and on account of the greater capacities that could be obtained from the boilers by that method of firing, also because boilers so fired could be made to respond more readily to sudden changes in load incident to peak-load stand-by plant operation than by any other method of coal firing, powdered-coal firing was chosen for the 60,000-kw. 1926 extension to Charles R. Huntley Station.

To obtain data for designing the furnaces under four cross-drum boilers which were purchased to deliver 200,000 lb. of steam per hour, an experimental furnace was installed under one of them. Maximum ratings were in mind and 275,000 lb. per hr. evaporation was obtained.

The paper shows how these experiments, on a furnace designed to remove the ash in the dry form, led to the development of the slag-tap furnaces for the 1926 extension and again for the 1928 extension, where the ratings were increased still further.

The performance of the slag-tap furnace has exceeded the expectation of its designers. Some of its advantages from both the design and operating standpoint are here enumerated:

It requires a minimum of building volume
It will burn efficiently and at high ratings an unusually wide variety of coals
It produces quick ignition of the fuel
It prevents infiltration of air into the bottom of the furnace
It requires a minimum of ash-handling labor, and
The ash handling is remarkably free from dust and dirt.

THE evolution of the slag-tap furnace, which was first used at the Charles R. Huntley Station in Buffalo about three years ago, has played a very important part in the development of the powdered-coal-fired furnace. Fourteen furnaces so equipped are in daily operation, and twenty more are in the process of manufacture and erection. These furnaces will supply boilers which have an aggregated steaming capacity in excess of 10,000,000 lb. per hour.

The conditions which surrounded the development of the slag-tap furnace were as follows: The Buffalo General Electric Co., in the fall of 1925, decided to purchase four 12,500-sq. ft. cross-drum boilers, 11 tubes high, 44 tubes wide, with 20-ft. tubes 4 in. in diameter, and overdeck superheaters. The existing boilers, 12 in number, were all stoker-fired with an unusually large ratio of grate area to boiler area which permitted 300 to 400 per cent of rating to be obtained for peak-load periods, which might be continuous for weeks at a time. The decision had been reached to fire the new boilers added in 1926 with powdered coal by the direct-fired system. All four boilers were to be installed at once, and one furnace was to be rushed to completion for test in order to get data for the design of the furnaces which must be installed in time for the next high-load season. It was the aim of the designers to build a furnace that would efficiently burn, at high ratings, any coal normally offered in the Buffalo market.

Much of the coal which comes into the Buffalo market has ash of a relatively low fusion temperature, 1800 to 2300 deg. fahr., and a heating value of about 12,500 B.t.u. Some coals which come into this market at approximately the same price range have a higher heating value of about 13,700 B.t.u., and ash of a 2600-deg. fusion temperature, but these cannot be successfully burned on the stokers at the Huntley Station on account of their coking qualities, which prevent free flow of air through the fuel beds.

Ten years of experience driving stoker-fired boilers at 300 to 400 per cent of rating demonstrated that the performance of the furnaces depended largely on the quality of the coal being burned. The qualities of a coal which affect its burning characteristics could not be determined by laboratory tests, which give proximate or ultimate analysis and ash-fusion temperatures only. Often in comparing two coals, the one which showed the highest heating value by laboratory tests has shown the poorest performance on the stokers and has evaporated less water per pound of coal.

None of the engineers of the coal companies who visit this territory have been able to predict the performance of a coal from its chemical ingredients as shown by its analysis. The analysis and ash-fusion temperatures serve only as guides in predicting how a coal will burn. Certain coals burned freely and efficiently when being consumed at the rate of from 20 to 25 lb. per sq. ft. of grate area per hour, but when the rating was pushed up by burning twice this amount per hour, the increased furnace temperatures matted the coal together into a solid mass. In some cases this matting was a direct result of the low-fusion temperature of the ash, and in other cases it was due entirely to the coking qualities of the coal. In any event the poor fireman was helpless when the coal fed to his furnaces changed to a coal of either of these characteristics. In spite of all precautions a carload or so of this character would come through now and then, and it always seemed to appear at a time when extra large amounts of steam were required. The very narrow and definite limits which the stoker-fired furnaces had placed on our coal purchases caused the engineers of the Buffalo General Electric Co. to give much study to this angle of the problem.

The narrow limits referred to above for stoker-fired furnaces apply to a lesser extent to the conventional powdered-coal furnace. With the refractory-lined furnace the engineer was forced to burn a very high-fusion-ash coal if he operated his furnaces at their maximum efficiency, i.e., with a minimum of excess air. He might choose the other expedient of sacrificing efficiency by lowering the furnace temperature by the use of large amounts

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of excess air. In any event he was forced to operate his furnace at a lower temperature than that of the ash fusion of the particular coal which he was burning, as no refractory so far dis-

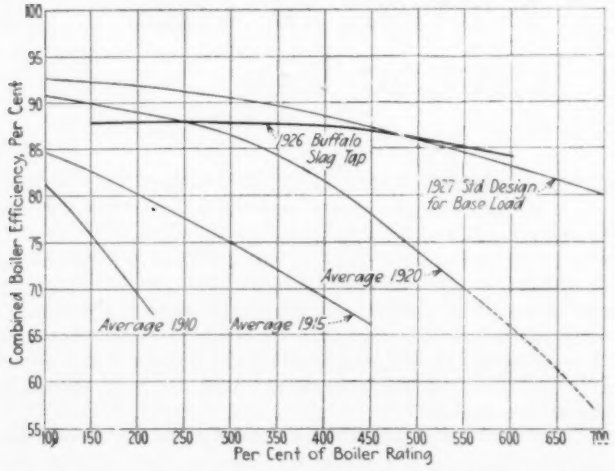

FIG. 1 AVERAGE EFFICIENCIES FOR STEAM-GENERATING UNITS, SHOWING IMPROVEMENTS MADE IN THE FUEL-BURNING AND HEAT-ABSORBING EQUIPMENT

covered will withstand the erosive action of molten ash running on its surface.

This is very clearly shown in Fig. 1 of a paper[2] presented by E. G. Bailey before the Annual Meeting of the Society in December, 1927. Mr. Bailey's paper also shows how sensitive the various powdered-coal furnaces are to this question of the ash-fusion temperature. It also shows how the ratings of the existing furnaces of the conventional refractory-lined type would have to be reduced if they were obliged to burn coals with lower ash-fusion temperatures.

All furnaces before the advent of the slag-tap furnace were designed for, and their successful operation depended upon, the removal of the ash in the dry form. Operators soon learned by bitter experience that if they did not so control the furnace temperatures that the ash was thrown down in a dry form, they would very shortly be forced to take the unit off the line until the solidified slag could be removed by pick and shovel.

Powdered-coal firing was chosen for the 60,000-kw. 1926 extension to the Charles R. Huntley Station on account of the greater capacities that could be obtained from the boilers by that method of firing, and because boilers so fired could be made to respond more readily to sudden changes in load incident to peak-load stand-by plant operation than by any other method of coal firing. The high ratings were shown to be economical for this plant, based on the assumption that the boiler-efficiency curves would drop off as rapidly as the 1920 projected stoker-fired curve, Fig. 1, shown by dotted line, would indicate. This figure shows in curve form plotted against rating, the average boiler efficiency obtainable in the different periods in the development of fuel-burning equipment.[3] Note the sharp decline in efficiency shown by the curves for the earlier periods. The narrow range of reasonably good combustion was caused by the low-set boilers of that day. The high point on the highest curve was obtained by providing a large amount of heat-absorbing surface beyond the furnace. The low-load-factor operation of the Huntley Station would justify the costs of only a moderate amount of heating surface. The actual efficiencies obtained on the 1926 boiler units appear in heavy solid line. The remarkably flat curve is due in part to the slag-tap furnace, as the high temperatures obtained permit the completion of combustion before the gases are chilled by contact with the boiler tubes. This minimizes losses from carbon carried over, or unburned gases. These tests[4] were reported before the Society in October, 1927.

The Buffalo General Electric Co.'s engineers, in laying out the experimental well-type furnace with its 8-ft.-square well,

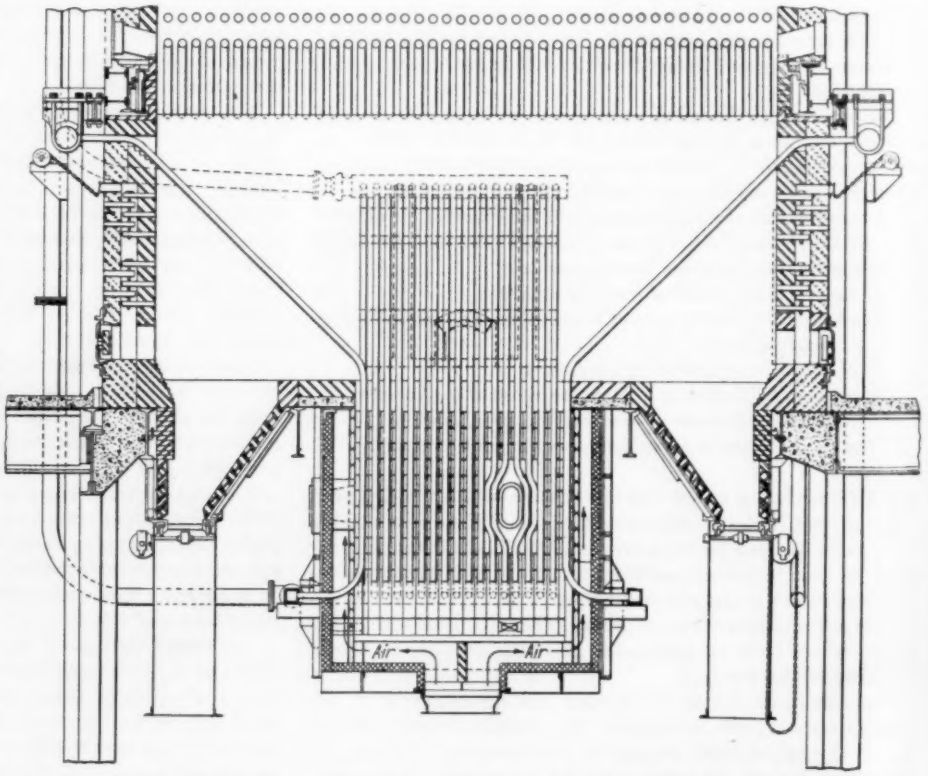

FIG. 2 CROSS-SECTION OF EXPERIMENTAL FURNACE NO. 13, SHOWING HOPPERS INTENDED FOR THE DRY REMOVAL OF THE ASH

hoped to be able to remove the ash in a dry state. They thought that the terrific velocity of the gases resulting from firing 20,000

[4] See Fig. 13, "Direct-Fired Powdered-Fuel Boilers With Well-Type Furnaces at Charles R. Huntley Station," by H. M. Cushing and R. P. Moore. Presented at the First National Fuels Meeting at St. Louis, Oct. 10–13, 1927. Trans. A.S.M.E., vol. 50 (1928), no. 8, p. 63.

to 35,000 lb. of coal an hour in this small well might prevent any accumulation of ash therein, and that the ash would all be carried up into the larger furnace above, where, as the gas expanded, it would settle down around the edges and later be hoed or shoveled into ash hoppers provided in the ends. (See Fig. 2.) A dry furnace did actually exist at first; but this was due to too cold a furnace. Only 3 in. of ashes had accumulated in the bottom of the well by the time that 3,000,000 lb. of water had been evaporated. Most of this was slag that had dropped from the boiler tubes above. A partial covering of tile was at this time put over the wall tubes above the well. After 4,300,000 lb. of additional water was evaporated, the furnace was tapped for the first time.

TABLE 1 COMPARISON OF BUFFALO SLAG-TAP FURNACES

Boiler No.	Heating surface, sq. ft.	Burner type	Method of firing	Furnace vol., cu. ft.	Excess air, per cent	Maximum lb. steam per hr., actual[1]	Heat liberation, B.t.u. per cu. ft. per hr. Total furnace	Heat liberation, B.t.u. per cu. ft. per hr. Below top of burners	Time coal enters until its gases leave Total elapsed sec.	Vertical speeds in ft. per sec. Furnace	Vertical speeds in ft. per sec. Well
Old 13	12,515	Calumet	Tangential	5,076	20	275,000	77,800	1,000,000	0.85	17	122
14–16	12,515	Calumet	Tangential	10,200	20	275,000	37,100	234,000	1.35	31	20
New 13	12,515	Cross-tube	Opposed	11,000	20	275,000	34,400	245,000	1.19	24	..
17–20	13,806	Calumet	Tangential	11,626	20	330,000	39,200	250,000	1.28	27	19

[1] These maximum evaporations are 10 per cent more than the continuous rating except for the experimental furnace where the continuous rating was cut down to 150,000 lb. evaporation on account of the severe punishment of the well walls at higher ratings.

While large quantities of ash came down around the edges of the larger furnace, both in powder and granular form, molten ash soon appeared in the bottom of the well and was tapped off as shown in Fig. 3. Note how the white-hot stream of slag, as it dropped some 7 ft. from the furnace bottom, disappeared into the pile of slag on the floor, the surface of which had been chilled by spraying water upon it. The cloud of steam in the background came from this cooling water. The molten slag having been quenched at one point to stop its flow from underneath this pile would soon break out at another point and proceed across the floor like a fiery monster. It was very fascinating to watch the action of this slag as it was tapped on to the boiler basement floor. One could spend hours watching the weird but fascinating spectacle.

The 1926 boilers and furnaces were bought to deliver 200,000 lb. of steam per hour. This expected output was immediately exceeded and evaporations up to 275,000 lb. of steam per hour were actually obtained from this boiler equipped with an 8-ft.-square well and a total furnace volume of 5076 cu. ft.

The volume of the well was 680 cu. ft. At the high ratings, 77,800 B.t.u. per cu. ft. were being liberated in the furnace and more than 1,000,000 B.t.u. per cu. ft. below the top of the burners. This latter value serves as a measure of the local punishment that was being inflicted on the furnace by assuming for the sake of comparison that all of the heat in the coal was liberated below the top of the burners. The heat-liberation values for the powdered-coal furnaces, other than for Buffalo and the experimental furnace at Bayonne, shown in Table 1 of Mr. Bailey's paper, above referred to, range from 12,200 B.t.u. minimum, (19,650 B.t.u. average) to 30,000 B.t.u. maximum, with maximum heat liberation below the top of the burners of 56,000 B.t.u. for Calumet and 57,000 B.t.u. for Narragansett, to compare with the corresponding values for furnace No. 13 of 77,800 B.t.u. and 1,000,000 B.t.u., respectively.

The extremely high values from No. 13 furnace were obtained as a result of the desire on the part of the designers to find the limit of punishment that the materials would withstand. For the other three 1926 furnaces, Nos. 14, 15, and 16, a furnace volume was chosen such that the heat liberation below the top of the burners was 234,000 B.t.u., and for the total furnace volume, 37,100 B.t.u.

In making these comparisons it might be of interest at this time to add the values for the four new 1928 furnaces and the rebuilt furnace No. 13. The 1928 furnaces were installed under boilers with 10 per cent more surface and were expected to produce 20 per cent more output. The furnace volumes were increased only 14 per cent; hence the corresponding heat-liberation values below the top of the burners became 250,000 B.t.u. and for the entire furnace volume 39,200 B.t.u. See Table 1. The rebuilt No. 13 furnace has a volume of 11,000 cu. ft. and comparative values for the heat release are: 245,000 B.t.u. below top of burners, and 34,400 B.t.u. for the entire furnace.

FIG. 3 ONE OF THE EARLY SLAG-TAPPING SCENES WHERE THE MOLTEN ASH FROM NO. 13 FURNACE IS DROPPED ON TO THE BOILER BASEMENT FLOOR

It became evident within two weeks after boiler No. 13 was first started that if the low-fusion-ash coals, which the plant was receiving at the time from mine-stripping operations, were to be burned, designs for the new furnaces must provide for the handling of the ash in the molten form.

It was demonstrated also, in the tests on No. 13 furnace, that the ash could still be removed in the molten form while operating with only one of the two pulverizing mills which normally supply this boiler. The maximum rating, as stated before, was 275,000 lb. of steam per hour, and the minimum with one mill operating, 60,009 lb.

The engineers realized that in deciding on a design to handle the ashes in a molten form they might be falling somewhat short of their original goal of designing a furnace capable of burning any coal offered on the Buffalo market. They reasoned, however, that the furnace conditions would automatically adjust themselves to give a higher temperature and the ash could still be handled in a molten form if they were required to handle the higher-fusion-ash coals, which so far had not been burned in furnace No. 13. Time would not permit of such a test before a decision had to be made for the design of the furnaces for the three other boilers.

Each engineer interested in this development had a different idea as to how this molten slag could be handled. They all agreed, however, that one or more of the schemes suggested offered a sufficiently practical solution to the problem to warrant the adoption at this time of the slag-tap design of furnace.

FIG. 4 LEFT: GRANULAR SLAG FROM SLUICE DISCHARGE; LEFT CENTER: SLAG TUBE FORMATION; RIGHT CENTER: MINERAL OR SLAG WOOL; RIGHT: SOLID BLOCK OF SLAG

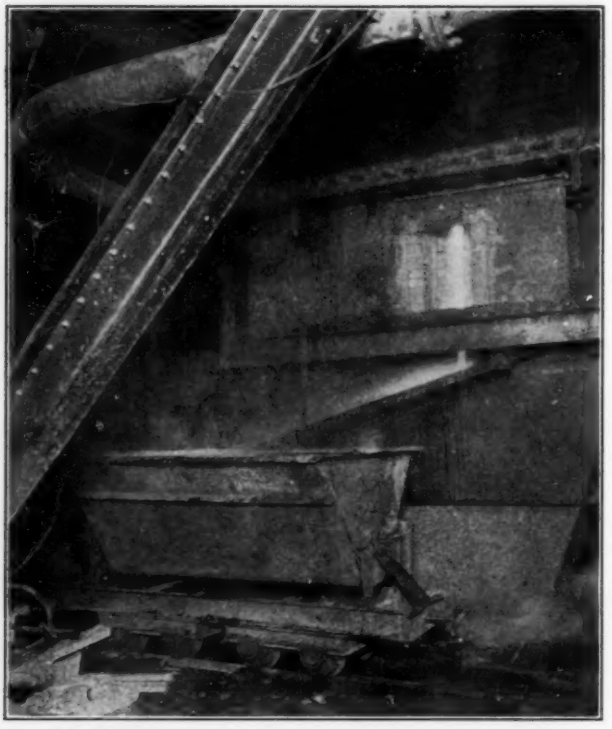

FIG. 5 TRIAL SLUICING OF THE SLAG FROM NO. 13 FURNACE INTO AN ASH CAR

At this stage of the development the engineers began to see the possibilities of obtaining much greater efficiencies at the extremely high loads than the performance of other furnaces had led them to expect. The adoption of the slag-tap furnace promised to be a help in that direction. It was argued that the hot bottom would increase the speed of ignition of the entering coal and air. The three T's of combustion again appear: Time, Temperature, and Turbulence. The Buffalo designs had slashed the time for combustion to a minimum, allowing the coal and its products to remain in the furnace only one and one-quarter seconds. It was necessary, therefore, to play up turbulence and temperature to a maximum. The hot bottom would unquestionably improve the temperature factor. The only point against the adoption of a slag-tap design was that it might possibly be necessary to choose only the low-fusion-ash coals for the new furnaces. For reasons previously stated this was not considered much of a handicap to the proposed new design.

To give a better picture of the problem, the following analyses of coal and slag are given, together with a few of the characteristics of the slag:

Coal (Dry Basis)	Per Cent
Fixed carbon	53.29
Volatile matter	34.66
Ash	12.05
Sulphur	2.85

Slag Analysis	Per Cent
Silica (SiO_2)	44.52
Aluminum oxide (Al_2O_3)	18.64
Iron oxide (Fe_2O_3)	31.35
Titanium oxide (TiO_2)	0.76
Phosphorus pentoxide (P_2O_5)	0.25
Calcium oxide (CaO)	1.33
Magnesium oxide (MgO)	1.10
Sulphur trioxide (SO_3)	1.80
Undetermined	0.25

Fusing point of ash, about 1950 deg. fahr.

When chilled into a solid state the slag had a very low coefficient of heat transmission, a fact that made it serve as a good heat insulation for the floor of the well. The lower part of the slag on the floor solidified due to the passing of secondary air beneath the bottom of the well. This low thermal conductivity also added to the problem of handling.

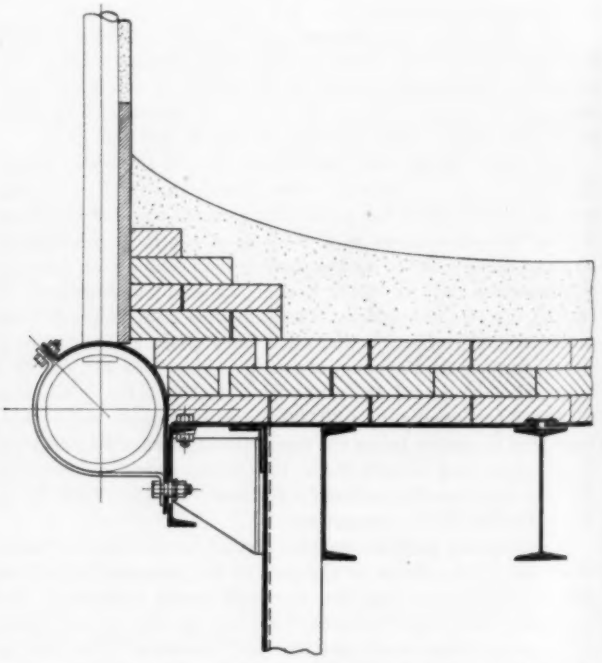

FIG. 6 DESIGN SLAG-TAP FLOOR SHOWING SLAG SEALS AT HEADERS

At a high temperature and below its melting point the slag was tough and viscous, like molten glass. When cool it was a dense black solid, often with a coppery opalescence at a fracture; it was hard enough to cut glass and weighed approximately 200 lb. per cu. ft. When running from the slag spouts into the open air the outer part of the stream congealed and the flow

continued through the center, forming a tube or pipe, one of which is shown in Fig. 4.

While the new furnaces were in the process of construction, experiments were made of dropping the slag directly from the furnace into a concrete buggy filled with water. To our great surprise no explosion occurred and there was little sputtering. The slag stream proceeded to form its own insulating tube to the bottom of the buggy and built up as if there were no water on top of it. The sheet-metal casing on the bottom of the buggy became red hot long before the surface of the water showed any signs of boiling. When the buggy was half-full of slag it was rolled to one side, and some fifteen minutes later it was emptied; the interior of the slag still being red hot.

Sluicing was then tried out by placing an 8-ft. length of 12-in. channel iron, sloped at an angle of about 30 deg., under the spout of the original boiler No. 13, and placing two $^3/_4$-in. water nozzles at the top so as to sweep the channel clean. (See Fig. 5.) The lower end discharged into an ash car.

These tests on sluicing led to observations that were of great value in arriving at the final solution. The slag stream was broken into small pieces by the mechanical force of the jets, and these pieces in turn tended to shatter into smaller pieces, owing to the rapid chilling effect of the water made possible by the exposing of greater surface areas per unit volume of slag. These facts indicated the necessity of using comparatively large volumes of water and were responsible for hydro-jet handling.

The design of the slag-tap bottom which has been installed substantially as shown on all eight slag-tap furnaces now in operation at the Huntley Station is shown in Fig. 6. A sheet-metal plenum chamber with angle and channel stiffeners is built on and rigidly supported from the boiler basement floor. This plenum chamber supplies the secondary air to the powdered-

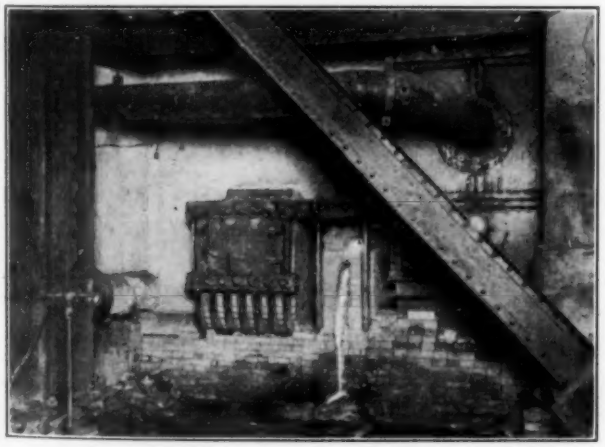

Fig. 7 Original Design of Slag Spout and Access Door

coal burners. The sides of the plenum chamber were made of concrete for furnaces Nos. 14, 15, and 16, but the later ones are all steel. The roof of the chamber is built very strong to support the furnace bottom with the load of from 24 to 30 in. of slag which might accumulate on it, also to take some thrust from the furnace side walls as they move up and down past this bottom. The maximum movement at this point amounts to $^3/_4$ in. Upon the 12-in. I-beams spaced 24 in. apart, $^1/_4$-in. steel plates are laid. Then three layers of a good grade of firebrick are laid—not too tightly—with their smallest dimension vertical. Around the edges four additional layers of firebrick are corbeled up to form a basin. About 6 in. of burned dolomite is then spread over the top. Slag from one of the other furnaces was used in place of the dolomite on the last furnace built, remodeled furnace No. 13, with equally good results. Special attention is called to the design of the slag and air seals, where the relative movement occurs between the furnace walls and the floor. It is very important that these are carefully assembled so that the parts cannot become unbolted and allow the molten slag to have a free path to the outside, which it is sure to find if cracks are allowed to open up. The cases where molten slag has gotten out on the floor have been caused by nuts not having

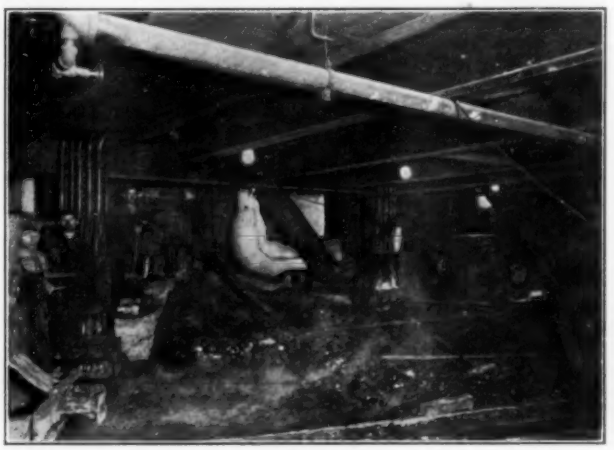

Fig. 8 Mass of Slag on Floor to Be Removed by Pick and Shovel

been put on in the first place, or having become loose and fallen off in operation. In the original job the workman could see no need of installing the nuts on the bolts which hold the bottom plates to the outside channels of the end walls, as it was impossible for these bolts to get out of place. He did not realize that as the boiler got hot it would push the lower header down about $^3/_4$ in. and carry this channel with it. The furnaces operated for months and nothing happened until after several consecutive 24-hour runs of one of the boilers at high rating, the slag broke through one evening, a couple of hours after the slag had been tapped very low, and several tons ran out on the floor to the consternation of the operators. The boiler was cut off the load as soon as possible and the hole soon froze shut. Being desirous of completing a test then in progress the boiler was put on the load the next morning, but at the end of another 48-hour run, broke out in another spot. The slag is a very good heat insulator and never has it broken out twice in the same place, nor has it ever broken out since the seals were properly put together.

In the original design the access door for the furnace was put at the bottom and adjacent to the slag-tap opening, so as to make use of a common header construction. Fig. 7 shows this construction. Back of the access door and in line with the furnace wall a 9-in. course of carborundum brick was laid up after each internal inspection to seal the opening. These bricks wasted away rather rapidly and the Bailey blocks adjacent to this opening could not withstand the punishment. These blocks had a great deal larger ratio of exposed surface in the furnace to tube-clamping surface than the other blocks in the well.

Note in Fig. 7 the slag as it starts to run on the floor and the loosely laid-up bricks protecting the lower parts of the plenum chamber. Fig. 8 shows the job which confronted the pick and shovel gang the next morning, with some 15 tons of ashes to be removed from the boiler basement floor.

The original tapping spout for the slag was made of firebrick supported on the circulating tubes for the water-wall headers,

as shown in the same Fig. 7. Fig. 9 shows the next step in this development. A hinged cast-iron spout permits the operator to raise the spout to stop the flow of slag, or to reduce the volume of an unusually large flow. The slag never sticks to smooth cast iron. As it cools its high coefficient of contraction makes its removal easy. The later designs of spouts are also of cast iron. They are attached to the water walls and equipped with

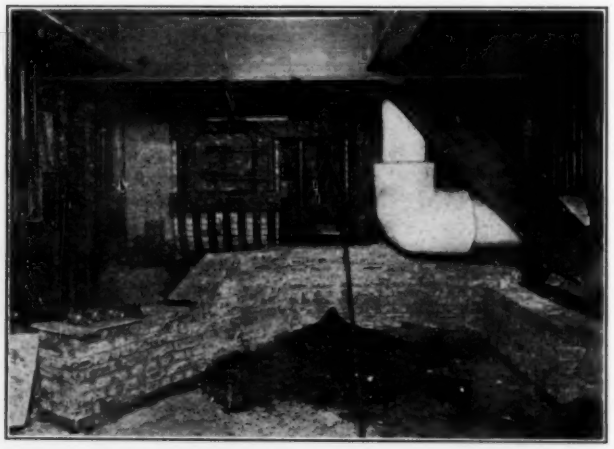

FIG. 9 HINGED CAST-IRON SLAG SPOUT

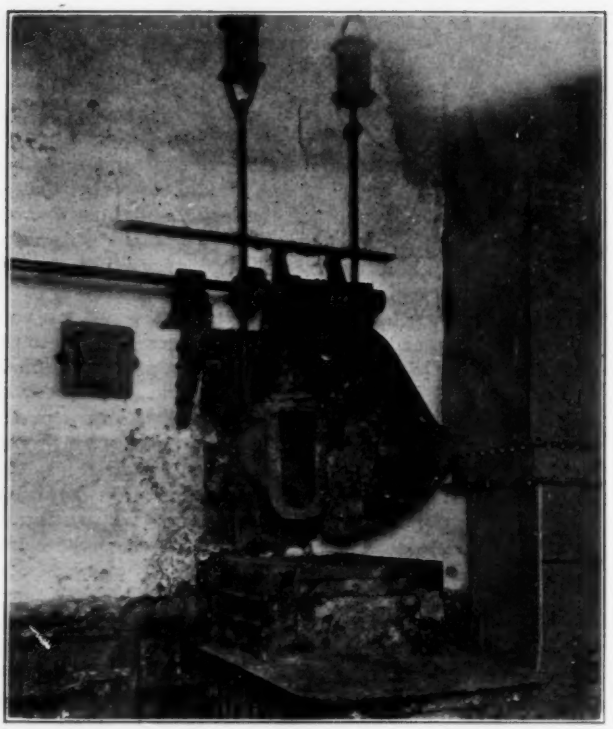

FIG. 10 WORM DRIVEN SLAG SPOUT GATE

chain-operated worm-wheel-driven cut-off gates operated from a point remote from the tapping spout as shown in Fig. 10. The gate as designed can be easily backed off by loosening a few bolts, which permit opening it should there be any binding from contact with the slag. It was expected that the gate would bind on account of the accumulation of molten slag behind it. This has not been the case. Although streams of slag 6 in. in diameter have been easily closed off with this gate, the gate has always been opened easily as soon as the slag behind it cooled. The cooling of the slag behind the gate leaves it in a very brittle condition, filled with shrinkage cracks which materially assist in clearing the tap hole for the next tap.

At the same time that the new design of tapping spout and shut-off gate were installed, the access door was removed from the bottom of the furnace and placed up in the V-shaped section of brickwork just below the main boiler tubes and above the water walls in the side walls of the boiler setting. An aluminum ladder especially designed to permit its use while the boiler walls are still hot has been designed. (See Fig. 11.) It is 30 ft. long and weighs 100 lb., and is flexible and can be easily inserted into and removed from the furnace.

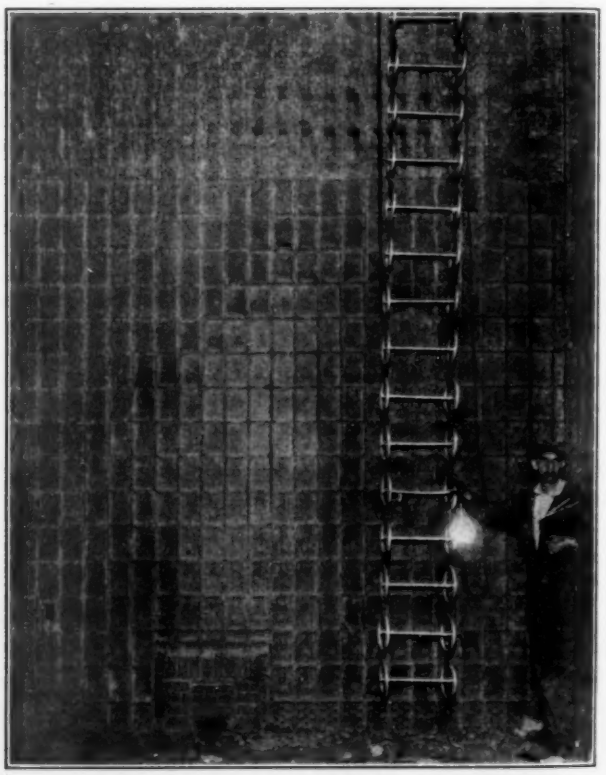

FIG. 11 FLEXIBLE LADDER FOR FURNACE ACCESS

As late as May, 1927, no definite plans had been agreed upon for the practical handling of this molten ash. Numerous suggestions had been made as to the best method of disposal of this slag, such as refractory-lined larry cars to handle the ash in a molten state; pouring the slag into water-jacketed cars; pouring the slag into water-filled dump cars direct from the furnace, somewhat as shown in Fig. 8; also various methods of sluicing the slag into a drag-chain conveyor which was run in water at the first part of its travel and then carry the chilled slag up an incline to the standard ash car used at the plant.

Not until all three of the new slag-tap furnaces Nos. 14, 15, and 16 had been put in service and the series of boiler tests had been completed, as reported at the St. Louis A.S.M.E. meeting[4] above referred to, was a satisfactory scheme of handling the slag worked out. Sluicing the slag had been seriously considered for some time, but the existing building beams would not permit of the installation of such a scheme if the existing practice of building sluiceways must be adhered to. Practice said

that right-angle turns introduced into such a system would lead to trouble. The manufacturer of this equipment, after satisfying himself that none other than right-angle turns would make a practical job at the Huntley Station, offered to furnish the material for a trial installation to be built above the boiler-room basement floor. The trial installation proved such a success from the start that the manufacturer was given orders to proceed with the manufacture of four equipments based on this first day's trial. The temporary equipment sluicing the slag into a hole in the yard continued in service until the permanent equipment was received. Fig. 12 shows the design of the sluicing system. The slag spout is not the latest design. The molten slag falls from the slag spout on to a water table formed by four primary jets of water, where it is cut into small pieces and partly chilled. Falling from here into a U-shaped cast-iron trough, it is then carried crosswise the building with the aid of two carrier jets for a distance of approximately 10 ft., and still further chilled in the process, owing to the additional cold water. This flow hits a cast-iron smashing plate, where it drops about 6 ft. and is turned at right angles into another U-shaped cast-iron trough running lengthwise the building and discharging

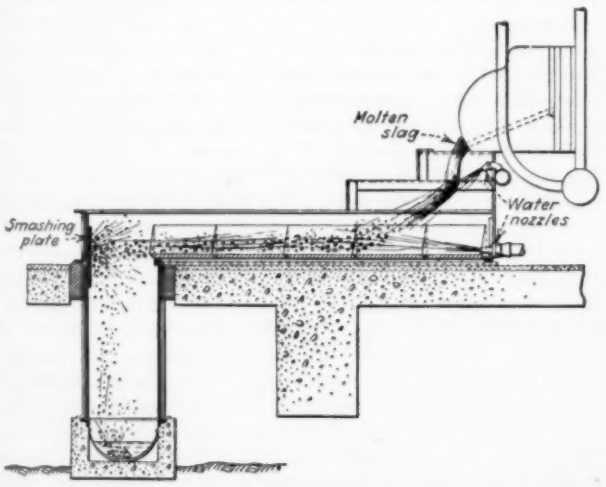

FIG. 12 SECTIONAL LAYOUT OF SLUICING SYSTEM

into a sump pit. Two additional carrier nozzles working in tendem are placed just behind the point where the slag strikes the lower sluiceway. The slag is deposited in a fine granular state at the discharge of the chute. Although pieces of slag 18 to 20 in. long, of a formation similar to the tubular specimen shown in Fig. 4, are often dropped into the sluicing system, they are hot enough though black in color to be shattered to bits in passing through the sluice. A grating is placed over the pit at the discharge from each sluice to catch pieces too large to be handled by the 4-in. diameter 760 g.p.m. vertical manganese-steel pumps, which are installed under the boiler basement floor. Two pumps are installed and are used alternately or together if a number of the boilers are being tapped at the same time to pump this slag a distance of 1000 ft. to the yard. Fig. 13 shows this discharge in service. All elbows in the suction and discharge piping are made of manganese steel. The discharge pipes are 6 in. in diameter and made of steel for the straight runs. The pipes are pitched to make them self-draining and are not insulated. Note that the material discharged spreads over a wide area instead of forming a pile beneath the pipes as had been expected. A pressure of 140 lb. is used at the sluice nozzles.

It is remarkable that this installation, which is the first to be designed for handling molten slag from boiler furnaces by the hydro-jet system, should have proved so successful from the start. Had not the low furnace-floor levels of boilers 14, 15 and 16 made the handling of this slag in the molten state by means of slag cars extremely difficult, this happy solution for handling it might not have been found.

Fig. 14 shows the molten slag discharging into the present sluicing system. This photograph was taken before the location of the access door was changed.

The question is often asked as to how the slag-tap design affects the slagging of the main boiler tubes. In the author's opinion, it lessens the slagging of the boiler tubes in a properly

FIG. 13 DISCHARGE FROM SLAG PUMPS

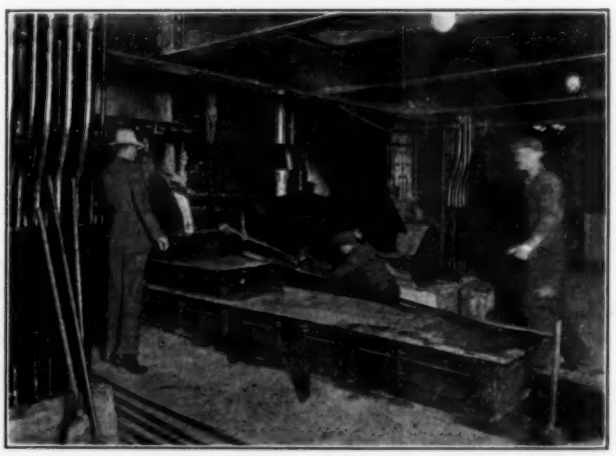

FIG. 14 PRESENT SLUICEWAY IN OPERATION

designed furnace in permitting the combustion to be completed lower down in the furnace, on account of the quicker ignition of the fuel.

The handling of low-fusion-ash coals at high ratings and with high efficiencies is one of the stiffest problems ever presented to a furnace designer. The paper has so far only dealt with the development of the slag-tap bottom for a slag-tap furnace. The walls themselves present an even greater problem. Obviously a slag-tap bottom cannot be successfully operated with any furnace whose walls will not withstand the action of molten slag running down its surfaces. This rules out the air-cooled refractory-faced wall for such service. It is the author's belief that only such walls are suitable for this service as will permit the molten ash to run down their surfaces, thus maintaining

the exposed part of the adjacent wall surface at a temperature at or above the ash fusion. The water-cooled refractory-lined walls that live under this service do so by virtue of the fact that the surface of the wall is maintained below the freezing point of the ash by its heat-conducting qualities, which carry the heat away from the surface exposed to the fire so fast into the water inside of the tubes that the wall-surface temperature is always kept below the ash-fusion temperature. This causes a layer of frozen ash to form over the wall, protecting it against further action of the slag and providing a self-renewing surface for the slag to flow over, for when the slag removes frozen slag by the erosive action of mechanical friction, a new layer is immediately formed. To make this self-renewing action possible the wall surface must no doubt be quite a lot cooler than the actual freezing point of the slag.

The formation of ash on wall blocks is very interesting. Examine a smooth water-cooled iron surface which may have an accumulation of frozen slag on it, and it will be found that it is very insecurely attached and will drop off at a touch if it is not otherwise attached to enable it to span this smooth surface. There seems to be a thin, fluffy slag between the bare iron and the solid slag, as if the first particles of ash to adhere to the iron were sufficiently cooled in approaching the relatively cold surface to deposit as fluffy ash.

The performance of the slag-tap furnace has exceeded the expectation of its designers. It has many advantages from both the design and operating standpoint; for instance:

It requires a minimum of building volume
It will burn efficiently and at high ratings an unusually wide variety of coals
It produces quick ignition of the fuel
It prevents infiltration of air into the bottom of the furnace
It requires a minimum of ash handling labor, and
The ash handling is remarkably free from dust and dirt.

Discussion

HENRY W. BROOKS.[5] Far-sighted engineering good judgment plus the courage of his conviction characterizes a contribution to fuels-engineering history by Mr. Cushing and his staff, which ten or twenty years from now even more than today we shall look back on as one of the outstanding developments of the fuels-engineering arts. For at least fifty years past, ever since man began to appreciate the efficiency possibilities of high-temperature furnaces, every effort has been concentrated, in boiler-furnace practice at least, either on the prevention of slag or the minimizing of its destructive effects.

Suddenly Mr. Cushing and his associates, based on their study of experiments, which though carefully done, were *only* experiments, decided to cast away all previous experience in this regard and to solve a difficult problem in an entirely new way. As it was the writer's privilege to work with Mr. Cushing and his associates during these days, perhaps no one else can so well appreciate to just what extent Mr. Cushing hazarded his engineering reputation on the success of this project. Once, however, Mr. Cushing had seen the character and extent of the experiments on the new form of combustion at Fullerton and had had an opportunity to study the results of this type of furnace at the Sherman Creek Station in New York, he became convinced that to generate peak-load power as an auxiliary to the cheap Niagara Falls hydroelectric power and to maintain anywhere near reasonably consistent costs required heroic treatment. He became convinced that the only possible means of accomplishing this, which the then state of the art permitted, was the type of furnace he adopted. To have talked of stations of initial cost of the usual $100 to $125 per installed kilowatt in this case would have been ridiculous, for the fixed charges alone would have necessitated selling at a loss on the basis of the low rates in the Niagara district. The problem put up to the engineers of the Buffalo General Electric Company was to design an efficient and workable plant at nearly half the usual accepted power-plant cost. They did it. They succeeded beyond their own expectations. In doing so, I am of the firm belief they have initiated a new era in the combustion of low-grade coals. Consider for the moment another view on this subject. Unquestionably the principal reason for the being of pulverized coal has been its claimed ability to burn with greater efficiency the lower grades of coals. Can this claim really have said to have been true prior to the Huntley installation? As one whose job for many years has been to cure "sick" powdered-coal jobs all over the United States, I am in position to answer this question unequivocally in the negative. Whenever low-ash-fusion coals had been encountered previously, trouble in large quantities always confronted the operator. If he obtained any decent rating out of his boilers, he did so at the expense of his dry-gas loss, for there was but one known method of combating wall punishment in those days and that was to decrease the furnace temperature by increasing the CO_2. Literally dozens of furnace walls, both solid and air-cooled, in my own experience, had buckled and in many cases fallen in, while in countless other cases wall erosion, due to slagging, had increased furnace-maintenance cost vastly beyond the savings which the pulverized-coal method made possible. The success of Mr. Cushing's furnaces once and for all definitely demonstrated the large-scale feasibility of abolishing the problem which for a time threatened the very existence of the newly developing powdered-coal art. As will be observed from the paper, this translation of scientific possibility into practical operating fact was not accomplished by a mere wave of the hand. No really successful technical accomplishment ever is, in spite of the natural enthusiasm of inventors. Fortunately, in this case the new-construction program had preceded the actual demand for steam by a sufficient period to permit ample experimentation before the equipment would be called on for steady service. As was expected, many minor difficulties had to be overcome. The fundamental basis, however, on which the design was made had been thoroughly proved, so that the application of calm, intelligent engineering thinking, with patience and perseverance, finally solved the problem. That the problem is solved and to the satisfaction of every one connected with it is demonstrated by the second installation of the same type as the first.

Financiers and company operating executives are notably hard-boiled when it comes to sinking hundreds of thousands of dollars into relatively new and untried projects. The fact that they did so the first time might have been attributable to incorrect judgment to which we are all prone. The fact that they did it the second time, however, coupled with world-renowned success of the property they direct, means that they must have had thorough proof that their initial judgment had been correct. Any one who has seen and studied the Huntley Station will not question this.

In conclusion, I think I am violating no confidence in telling you that the initial cost on this peak-load station, even including all of the experimental work which has gone on there, has been approximately one-half the initial cost of the average of all similar generating plants which have been built in the United States in the last four years. The initial cost of this plant is so far lower than its nearest competitor along these lines that Mr. Cushing has only preserved his engineering veracity at the expense of reticence on a subject vitally important to the entire engineering field. Furthermore, based on monthly operating logs which I

[5] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

had the privilege of seeing when last in Buffalo, taken at random since the initiation of this new development, I find, much to my surprise, that the overall station economy in B.t.u. per kilowatt-hour is exceeded by but few stations in the United States. I should be violating a confidence if I told you just how low these figures are, but I believe that I can say that they are within less than 2000 B.t.u. of the most efficient station now existing in the world. As I happen to know that this latter station cost initially more than two and one-quarter times as much as the Huntley addition and as all of us are familiar with what a large bearing the fixed charges have on the total average cost of generated central-station power, I think it can be safely said that, on an equivalent coal price, Huntley Station is today perhaps the lowest-cost generating station in the world. I may also add my observation that the accomplishment of this is at least 90 per cent attributable to the ability and foresight of Mr. Cushing and his associates.

E. J. Billings.[6] The author is to be congratulated upon this very frank report of his experiences and the fact that he has always given freely to the engineering profession the benefit of his experiences in handling ash from a boiler furnace in liquid form.

Liquid-ash removal or the slag-tap furnace is recognized by the leading engineers as a development which has permitted the art of pulverized-coal firing to overcome one of the most difficult problems connected with this method of burning coal. The limitations of pulverized-coal firing as pointed out by the author have not in the past primarily been in the pulverizing and burning equipment but in the furnace design. The slag-tap furnace with proper water-cooled construction now makes it possible to design suitable furnaces that are capable of handling coals having wide ranges of moisture, ash, and ash-fusing temperature.

The merits of this method of ash removal are evidenced by the fact that there are 17 slag-tap furnaces of one particular manufacturer's design that are now in daily operation and 26 others in the process of design and erection.

The results of an investigation of a large block of slag taken from the center portion of a slag-tap furnace floor after the boiler had been operated over a period of $2^1/_2$ years are of considerable interest. The block was approximately 18 in. thick from the top surface of the slag. Various analyses were made from samples taken at different elevations, as shown in Table 2.

TABLE 2 ANALYSIS OF BLOCK OF SLAG

Distance from top, in.	Per cent					Fusing temp., deg. fahr.
	SiO_2	Al_2O_3	FeO	CaO	MgO	
1/2	39.03	23.86	34.30	1.40	1.41	2045
5	39.63	22.90	33.86	1.54	1.34	2045
9	38.50	23.78	35.06	2.40	1.64	2065
13	28.06	25.58	32.14	9.70	3.73	2140
16	29.80	27.05	18.30	10.20	13.44	3000

It will be noted that down to the 9-in. elevation the fusing temperature remained substantially constant, and at the 16-in. elevation slag penetration has not been sufficient to lower the high-fusion filler, which in this case was burned dolomite. The rapid increase in CaO and MgO below the 9-in. elevation also attests this same condition.

The furnaces at Buffalo have a plenum chamber beneath them which permits circulation of the air used for combustion on the under side of the steel plate supporting the furnace floor. Although this is an expedient for this particular burner and furnace arrangement, it is not essential that the floor be cooled in this manner. If the supporting steel is arranged so that there are no air pockets formed on the under side of the furnace floor, natural circulation of boiler-room air is sufficient to keep the floor-supporting members from being overheated.

The flexible ladder which the author mentions for furnace access is a very ingenious piece of equipment. One man can handle this ladder very conveniently.

F. B. Allen.[7] Mr. Cushing has quite thoroughly outlined the method of molten-ash handling employed at Buffalo. It so happens that the writer, together with other engineers of the company with which he is associated, spent considerable time at Buffalo in connection with this problem; in consequence, there are certain details that he feels might be emphasized.

The fundamental principle consists in tremendously increasing the area of molten ash, at the same time reducing it to smallest practical size while it is in the molten state. After this has been done it is of course relatively easy to chill each particle below its fusion point, because

(*a*) As there are literally millions of particles per ton, the total area per ton is extremely large, and as all or most of this area comes in contact with water, the heat release is tremendous.

(*b*) As all or most of the particles are very small, their maximum thickness is insufficient to allow the surface of the particle to be chilled while the center of the particle remains molten.

Although as Mr. Cushing says the ash-handling system has been successful from the first, yet minor difficulties have developed which had to be met as they appeared, such as:

1 It is important that the water table discharge parallel with the flow of the slag down the spout. It should not be at right-angles to this flow, because the quantity of slag discharge varies tremendously; in consequence, the path of the ash will vary nearly a foot from maximum to minimum discharge, and if the primary jets forming the water are not parallel with the flow, the slag may not reach or may partially override the table.

2 Care should be taken that the water quantities are sufficient for the maximum slag discharge, and as this is perhaps twice the average it is probable that considerable power could be saved by the installation of valves that would allow of the gradual reduction of water quantities after the first floods of slag had subsided.

3 Horizontal manganese-steel pumps were originally installed for pumping the disintegrated ash particles together with the water out of the plant. These operated very well, but had the disadvantage that (as they necessarily were installed) they had to be primed before starting, and occupied valuable floor space on the mill floor. Later, therefore, vertical pumps were installed. Detail troubles developed in these pumps. It was found that the stuffing box along the shaft gave trouble, as it was impossible to adequately inspect it. The pump was redesigned so as to omit this. Other troubles followed, most of which resulted from difficulty with the bearing below water. These are being met as they develop.

It was also found very difficult to operate two pumps through a common discharge line, and a second discharge line, one for each pump, was later installed.

From the standpoint of a manufacturer of ash-handling machinery the writer can say that the most outstanding feature of the installation made by Mr. Cushing and his engineers is its absolute cleanliness. There simply is no dust from the ashes, as none of the ash is in the form of dust.

Another thing that clearly stands out is the thoroughness with which Mr. Cushing and his engineers attacked the ash problem. Every furnace of the slag-tap design put in operation since Buf-

[6] Vice-President in Charge of Sales, Fuller-Lehigh Company, Fullerton, Pa. Mem. A.S.M.E.

[7] President Allen-Sherman-Hoff Company, Philadelphia, Pa.

falo, so far as is known by the writer, uses substantially the same ash-handling principles.

Author's Closure

The data presented by Mr. Billings, as to the composition of slag from various depths in the floor of the slag-tap furnace, are very interesting and show how little effect the composition of the floor has on the fusing point of the main body of ash. The tests made on one of the Baffalo furnace bottoms confirms the information given by Mr. Billings, that forced circulation of air underneath the steel-plate floor is unnecessary provided free unpocketed natural circulation is available. In this experiment the supporting steel I-beams were insulated with $^{7}/_{8}$-in. matched lumber, sealed with tar paper. Thermocouples placed on the top flanges of the I-beams adjacent to the steel-plate bottom showed a maximum temperature of 200 deg. fahr., which maximum temperature was more than 50 deg. hotter than the operating temperature and occurred as a gradual rise when the furnace was cut out of service. The furnace was operated during this test from ten to fourteen hours each day for a week at about 450 to 500 per cent of rating.

The principles underlying the successful handling of molten slag by hydro-jet system are clearly set forth in Mr. Allen's comments. The manganese-steel horizontal pumps of which Mr. Allen speaks were in service for more than 18 months, handling all the slag from four furnaces, and have been in intermittent service during the last nine months, handling slag from eight furnaces. It is interesting to note that in the handling of this highly abrasive material, no pump parts, with the exception of bearings, have had to be replaced.

Proprietary Air-Cooled Refractory Walls

Evolution of the Boiler Furnace—Forms of Patented or Proprietary Air-Cooled Refractory Walls Now Available—Data on Performance of Air-Cooled Walls in Service

By C. S. GLADDEN,[1] DETROIT, MICH.

This paper discusses briefly (1) the evolution of the boiler furnace and the increasing tendencies toward higher ratings of boiler operation and the attendant increasing maintenance troubles with refractories; (2) describes some of the proprietary air-cooled walls now available for the consideration of designing engineers and boiler-plant operators; (3) gives the operating experiences of certain engineers with air-cooled refractory walls of different types, and (4) presents the author's opinion concerning the conditions suitable for air-cooled refractory-wall installations.

THE author of this paper does not pretend to present all the facts and figures that may or may not be available to definitely establish rules for determining when air-cooled furnace walls should or should not be used for boiler furnaces. Engineers interested in combustion problems differ widely in their opinions concerning this subject, and this difference of opinion is often justified by the particular angle or point of view from which they approach the subject.

This paper, then, will attempt to trace, in a sketchy fashion, the evolution of the boiler furnace, describe the forms of patented or proprietary walls now available, and present certain data concerning the performance of walls which have been in service.

EVOLUTION OF THE BOILER FURNACE

About 160 years ago Watt was engaged in improving and in developing new features of the first steam engine. The boilers furnishing the steam for these engines are not described in engineering literature, but they are supposed to have been of the cylindrical shell type, fired externally with coal in furnaces constructed with some sort of refractory materials.

About 20 years after the historic date, 1769, that Watt began his improvements of the Newcomen pumping engine, we read of the first successful attempts, by James Rumsey, to construct water-tube boilers in the United States, although patents for several forms of boilers of this type had been previously brought out in England. Numerous forms of water-tube boilers were developed during the next 60 or 70 years, but the art of boiler construction at that time had not advanced sufficiently to place their manufacture among commercially successful enterprises. On the other hand, the shell type of boiler was comparatively easy to build.

The boiler used by Fulton in the *Clermont* and by Stephenson in the first locomotive was designed with a single flue lengthwise through the lower part of the main boiler shell. Soon after the development of the first locomotive and the first steamboat, horizontal return tubular boilers and Scotch marine-type boilers were constructed. The return tubular boiler required a furnace and setting constructed of refractory walls, while furnaces of the internally fired boilers were water-cooled.

For a considerable period of time the horizontal return tubular boilers were extensively used in connection with steam generation for stationary practice, and not until the first Babcock & Wilcox boiler was brought out in 1867 did the manufacture of water-tube boilers become commercially successful. Both the horizontal return tubular boilers and the early water-tube boilers were set in brick settings with refractory furnace walls. The boilers were set low, close to the firebed; smokeless combustion was not then given serious consideration. During the same period of time the boilers used in connection with transportation, for locomotives and steamboats, were entirely of the internally fired water-cooled firebox type. Thus, we have the two types of construction of furnace walls being developed simultaneously in the two fields of steam-power development.

The next forward step in steam generation was that of mechanical stoking. The primary purpose of this phase of steam-generation development was the elimination of manual labor in stoking, but another very important result was the ability to obtain increased evaporation per square foot of heating surface, since the combustion of more coal per square foot of grate area became possible. However, maintenance troubles were experienced with the refractories in the furnaces.

In 1875 Thomas Murphy began the experimental development work of the Murphy stoker on his dredge operating on the Great Lakes. In 1880 the first successful installation of the Murphy stoker was made in one of the plants of the Cambria Steel Company. In 1888 Wm. R. Roney introduced the first Roney natural-draft stoker, which was extensively used for 30 years. In the same year, 1888, Evans Jones invented the underfeed retort type of stoker which has since been used in many of the smaller boiler settings. The introduction of the inclined underfeed type of stokers, pioneered by the American Ship Windlass Company in the plant of the Narragansett Brewing Company at Providence, R. I., in 1905, materially changed boiler-furnace conditions and requirements. Again the rate of combustion per square foot was increased, boilers were raised to higher elevations above the fuel bed, furnace volumes were increased, and smokeless combustion was achieved. The furnace walls required still greater care and engineering skill in design and construction to avoid expensive maintenance.

The introduction of pulverized fuel has again altered the service required of furnace refractories. The competition of pulverized-fuel combustion with the burning of fuel on modern underfeed stokers has served to bring about a constantly increasing rate of evaporation per square foot of heating surface in the boiler, larger furnace volume, and an ever-increasing number of problems in the design of the furnace walls. The use of fuel oil and refuse wood from furniture and automobile-body manufacturing plants has also created severe conditions for furnace refractories to meet.

Until recently, wherever refractory-arch construction was required, the arches were supported only by the skewbacks from which they were sprung. As the development of the stoker became more and more perfected and higher boiler ratings were being obtained, increasing difficulties with sprung arches in the combustion chambers were encountered. The Laclede Christy Company introduced a suspended arch with a chain-grate

Contributed by the A.S.M.E. Special Research Committee on Boiler-Furnace Refractories and presented at the Rochester Meeting, Rochester, N. Y., May 13 to 16, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

stoker in 1907; M. H. Detrick installed the first Detrick arch in 1911; the first Bigelow arch was installed in 1916; the Liptak double-suspended arch in 1918, the DeWolf arch in 1920, the American arch in 1921, and the McLeod & Henry arch in 1922. Considerable savings were effected in the maintenance cost of arch construction. Since the World War, nearly all well-designed boiler furnaces requiring arch construction have been built with suspended arches.

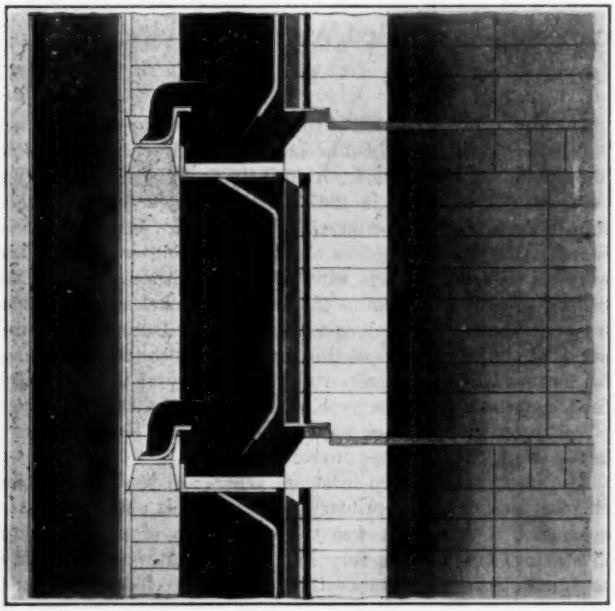

FIG. 1 CROSS-SECTION OF DETRICK WALL

The next important development in furnace-wall construction was that of the supported side wall, which may be air cooled. These walls proved quite satisfactory for the operation of boilers at ratings less than 250 per cent.

With the introduction of pulverized coal and boiler ratings in excess of 250 per cent the air-cooled refractory side-wall construction has not in all cases proved entirely satisfactory. So-called water-cooled side walls have been introduced, in which the refractory walls are protected with tubes through which water passes in connection with the circulation in the boilers. These tubes may be placed adjacent to the wall on the inside of the furnace, the entire furnace wall may be constructed of tubes with a small amount of refractory and insulating material on the outside, or the tubes may be arranged with strips of steel fin-like in form welded to the tubes to present a solid iron surface to the fire. We also find a combination of water-cooled and air-cooled walls in which the water-cooled surfaces are subjected to the more severe conditions and the air-cooled surfaces to the less severe conditions within the furnace. Thus, in stoker-fired installations with bent-water-tube boilers we find designs in which water-cooled walls are used for the bridge wall and for the side walls in the zone in contact with burning fuels. Above these zones of most severe conditions, and in the front wall many modern installations are using air-cooled suspended side-wall construction.

An interesting illustration of the development of boiler furnaces is furnished at the River Rouge plant of the Ford Motor Company, the boilers for which were originally designed to generate 250,000 lb. of steam per hour and were constructed with solid refractory walls, the secondary air for combustion being ad-

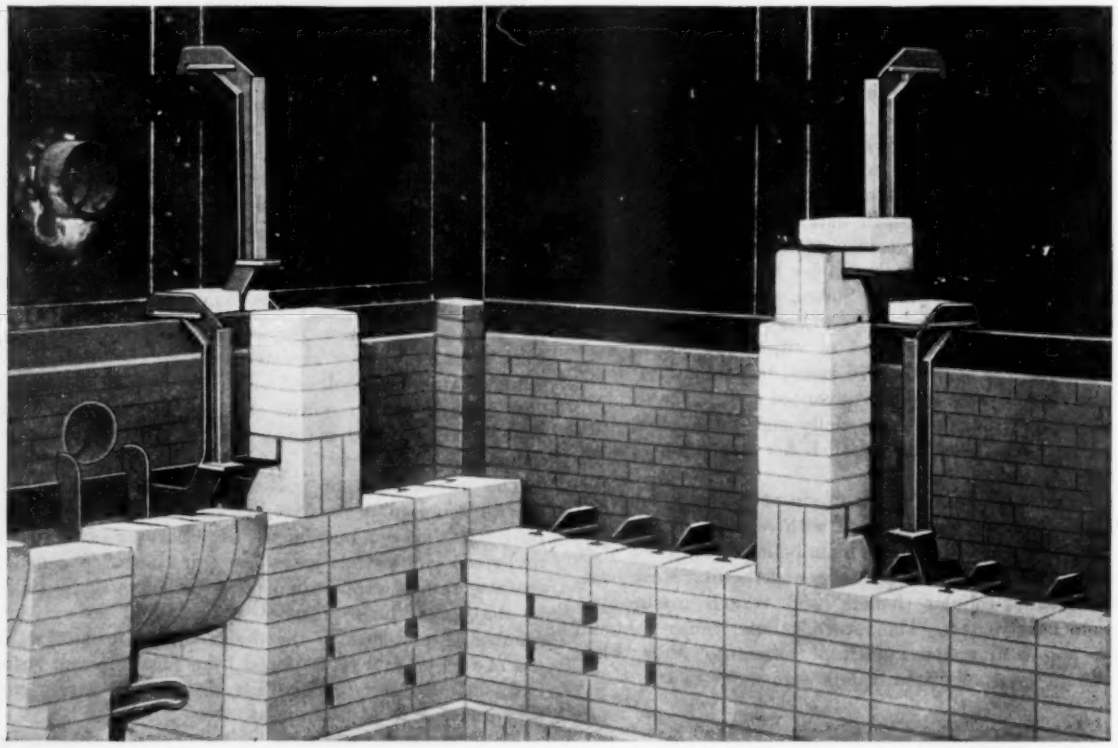

FIG. 2 GENERAL ASSEMBLY OF DETRICK WALLS

mitted through ports in both front walls of the double Ladd boilers, entering the furnace in the immediate vicinity of the pulverized-fuel flames. When it became necessary to increase the steam production of this plant a change in the furnace settings was made in which the side-wall construction was replaced by water-cooled construction. Here the air for combustion is preheated in air preheaters and is admitted with the pulverized fuel through specially designed nozzles around the burner and through ports in the front walls. With this construction the same boilers have been increased in capacity to produce 500,000 lb. of steam per hour.

AIR-COOLED REFRACTORY FURNACE WALLS

Air-cooled refractory walls may be segregated under two general classifications; namely,

1 Walls in which special refractory shapes are definitely held in position by structural steel and cast-iron members which also support the weight of the refractories; and

2 Walls in which special refractory shapes for furnace lining are bonded to the main wall but are not supported thereby.

The wall construction of the first group will now be described.

The Detrick Wall

The M. H. Detrick Company's first wall was installed in the

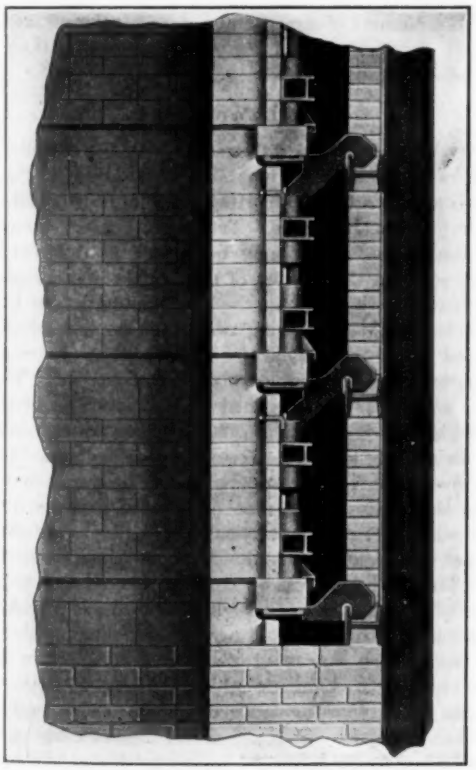

Fig. 3 Cross-Section of American Arch Company's Wall

plant of the Binghamton Light, Heat & Power Company at Binghamton, N. Y., in 1924.

The design and methods of construction of the Detrick wall are indicated by Figs. 1 and 2. This wall requires three forms of blocks for its construction. As will be seen by referring to the illustrations, it consists essentially of independent sections, each $10^1/_2$ in. wide by 30 in. high. The wall sections are placed side by side in horizontal bands. The wall tiles are placed adjacent to each other with plastic clay applied in the vertical joint. Each joint is sufficient for any expansion due to heat that may occur; however, the precaution of laying up corners in such a manner that expansion may take place freely is usually followed. The face tile are $10^1/_2$ in. wide by 3 in. high and are

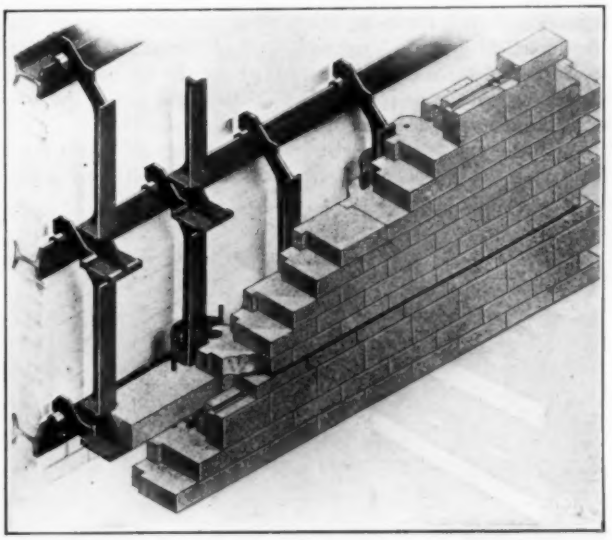

Fig. 4 General Assembly of American Arch Company's Wall

10 in. in depth, and the distance from the face of the tile to the slot which receives the T-head of the cast-iron bracket support is $7^1/_4$ in.

The cast-iron hangers are arranged with a horizontal shelf near the base to support each integral section independently of all other sections. They are carried on horizontal girders attached to vertical columns which support and maintain the alignment of the entire wall. They also serve as heat conductors from the grooves in the tiles to the cooling air surrounding them. The upper end of the hanger hooks over the edge of the horizontal girder, and the lower end thrusts against the girder below. No bolts or fastenings are used, so that the hangers are free to move should the expansion of the wall be sufficient to cause such displacement.

The hangers are provided with suitable flanges for supporting baffle tiles or plates which may be placed horizontally between the hangers to form horizontal lanes or passages for the air. If these baffles are omitted, vertical circulation of air may be obtained. The outside of the air passage or the outside face of the furnace wall is usually a single course of red brick, although steel plate or other material may be used.

The American Wall

The American air-cooled side wall has been applied to a considerable number of important boiler installations. Its general construction is shown in Fig. 3, and the method of bonding and of attaching alternate courses to the cast-iron supporting bars is indicated in Fig. 4. The wall is made up of independent horizontal sections 30 in. high, each section consisting of nine courses of special blocks which are attached to the cast-iron hangers. Five different shapes of refractory blocks are required for this construction. For each section there is first a course of supporting tile resting on shelves at the lower end of the hangers; then seven courses of 3-in. × 9-in. × 9-in. tile with

offset vertical joints in two shapes, one with a hole in a projection in the back of the tile to receive the pin of the retaining yoke located at each alternate hanger, and the other with a straight back surface; then a thicker course of one special shape grooved in the top surface and held in position by tee anchors; and finally, at the top, a course of sealing tile with a tongue or ridge to fit into the groove of the tile below. All courses bond over the course below and the corner construction is bonded without provision for a slip joint, the horizontal expansion of each tile being taken up in the vertical joint. The offset vertical joint is designed to reduce the infiltration of air. It will be noted that the effective depth of the tile extends from the inside face to the pin in the cast-iron yoke and is the same as the full depth of the tile, or 9 in.

The lower end of each cast-iron hanger rests against the top of the hanger below. The hangers hook over 5-in. H-beam girders

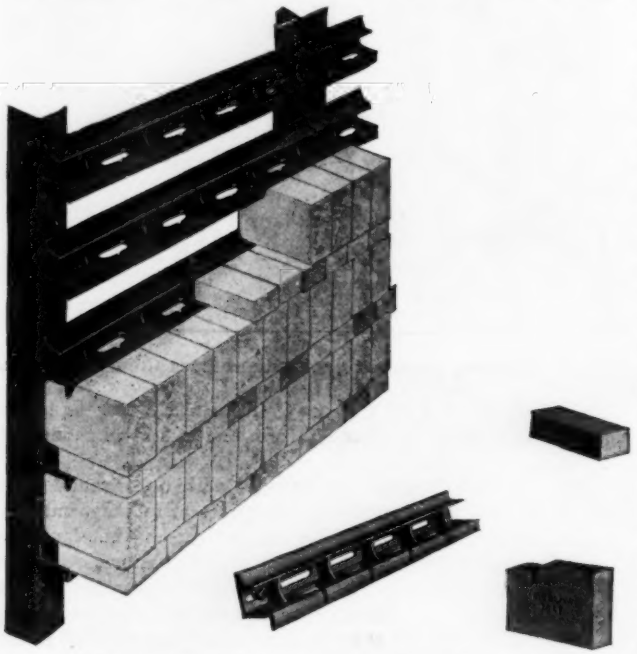

FIG. 5 BIGELOW SUSPENDED FURNACE WALL

which are attached to vertical steel members. The yokes which surround the back of the hangers and hold the tile in place are not attached to the hanger but are free to move with any vertical expansion. Air lanes may be arranged as desired with suitable baffling between the furnace tile and the exterior curtain wall or covering.

THE BIGELOW WALL

The first installations of Bigelow air-cooled side walls were placed in service in the oil-still furnaces of the Freedom Oil Company in April, 1925, and were first installed in boiler-furnace construction in the same plant in November of the same year. They have since been successfully installed in the furnaces of many boilers, the largest to date being 1510 hp. The construction of this wall is illustrated by Fig. 5. It consists of a single special type or design of block and standard firebrick. Each block is independently supported and is therefore free to expand in all directions within the limits of the vertical and horizontal joints. The blocks are supported in horizontal bands as shown in the illustration by means of horizontal bracket castings bolted to vertical steel members, which may be either I-beams or built-up columns with angles as flanges. They are laid in courses spaced $10^3/_4$ in. center to center vertically, with one course of standard firebrick laid as headers between each course. The special blocks are 11 in. in depth, and the distance from the face of the cast-iron bracket to the inside of the wall is approximately $7^1/_2$ in. The block is 4 in. in width and 8 in. high. The $^1/_8$-in. joints on top and underneath the course of blocks are filled with a special plastic fireclay. The vertical joints are formed by dipping the blocks in this special fireclay batter and placing the tile in the wall firmly together. To remove or repair any section of this wall it is only necessary to remove the firebrick above and below the block, when the block may be taken out by tilting it upward. This construction involves vertical joints between the blocks 8 in. high. The blocks are either hand molded or dry pressed. The latter process insures accuracy in size, and the vertical joints are reduced to a minimum and yet are sufficient to allow for the expansion of each block.

The air circulation, when I-beams are used as supporting members for the wall, is vertical. The outside of the column may be covered with steel plate, which may be insulated if desired, or with a thin brick wall. The natural chimney effect of the air between the vertical columns heated by the furnace lining is sufficient to circulate the air required for cooling the walls, and is controlled by adjustable dampers or predetermined orifices. In many cases the air after circulating past the heated walls is recovered and used for combustion. If horizontal circulation is desired a built-up supporting member may be used, constructed with two pairs of angles riveted to steel crosslacing or spacing plates, spaced as desired to form horizontal circulation. The amount of preheat absorbed by the air varies from 50 to 150 deg. fahr., depending on the rating and the extent of air-cooled side wall used.

THE DEWOLF WALL

The DeWolf air-cooled wall was first used in a boiler-furnace setting in 1924. Its design is shown in detail in Fig. 6. In this construction the supporting tiles are attached directly to the vertical steel I-beams. Turning to Fig. 6, reference No. 1 shows the beams, which may be spaced at different centers. The difference in the spacing of the centers is accomplished by using three lengths each in the two standard face blocks, so that for the minimum spacing two of the smallest blocks would be placed end to end, while for the maximum spacing two of the largest blocks would be placed end to end. The intermediate spacing is accomplished by combinations of the three sizes of blocks. Reference No. 2 illustrates the cast-iron clamp which secures the hanger brick to the steel column. Reference No. 3 shows the regular A-type hanger brick, each of which engages the ends of four face brick with grooves fitting the tongue which forms the vertical edges of the anchor brick. Reference No. 4 illustrates the A2 type of supporting hanger brick. The A2 bricks rest on continuous angles or clips which are riveted or bolted to the vertical steel beams. The A2 hanger brick are longer than the A hanger bricks, thus forming a ledge in the front which carries all of the face brick above the ledge to the top of the 32-in. or 40-in. section. Reference No. 5 illustrates the supporting angle or clip which supports the A2 hanger brick. Reference No. 6 shows the assembly of the face brick attached to the lower A2 hanger brick and which are supported on the lower courses which in turn are carried by A2 hanger brick further down. Reference No. 7 shows the face brick which are attached to the A hanger brick and are supported by A2 hanger brick further down. The facing brick for both A and A2 hanger brick are 4 in. in height and are $7^1/_8$ in., $9^1/_8$ in., and $11^1/_8$ in. in width. This wall construction, therefore, is developed with eight forms of special blocks to accommodate

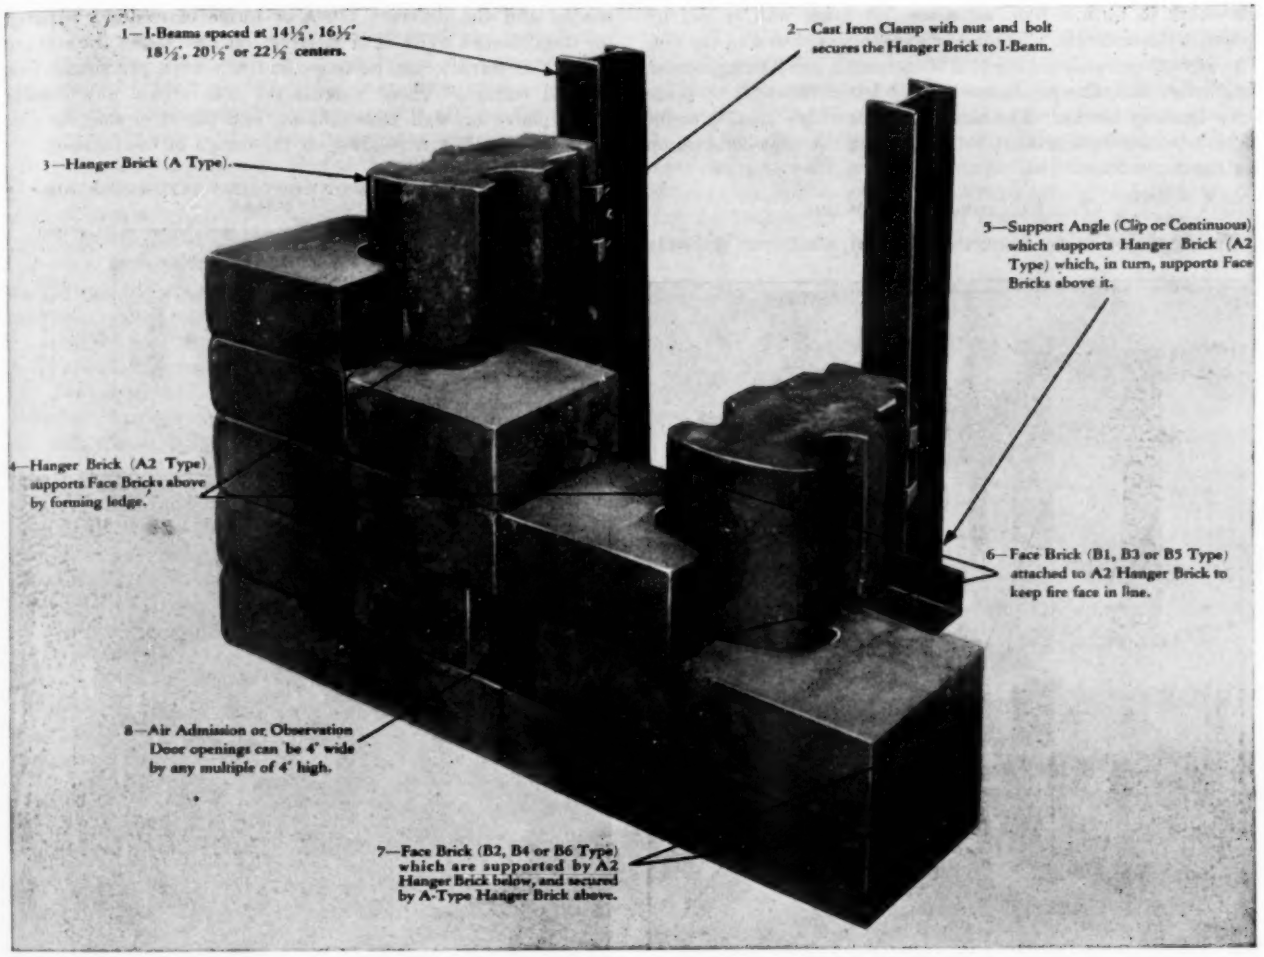

FIG. 6 CONSTRUCTION OF DEWOLF WALL

various spacings of vertical I-beams. If the vertical I-beams can be definitely spaced on the same centers, not over four blocks of different shapes will be required. No horizontal expansion joint is provided between the horizontal sections as it is considered that this is not necessary. In laying the wall plastic fireclay is placed between the horizontal and vertical joints of the face brick, but care is taken that no clay is placed in the joints between the face brick and the hanger brick.

The outside of the vertical beams is covered with steel plate to form vertical air ducts between the wall and the cover plates. The chimney effect or draft produced by the heated air is sufficient to cool the wall if proper openings are left at the top and bottom of the ducts. The air may be drawn through the ducts by a fan and, when heated, may be used for combustion.

THE MCLEOD & HENRY WALL

This wall design is the most recent of the supported air-cooled walls, the first installation having been completed last year. The construction of this wall is shown in Fig. 7. The wall is supported by cast-iron brackets in horizontal bands or sections 24 in. high, with a packed expansion joint between each horizontal section. Three shapes of wall tiles are required, the regular tile being 4 in. high, 12 in. wide, and 10 in. deep. The tiles are held in position by cast-iron clips which slip over the head of the vertical T-bars and fit into suitable recesses in the upper face of each tile. The cast-iron brackets are bolted to the upper flange of standard 9-in. channel beams, and the two braces of each bracket rest against the lower flange of the channel. The brackets are of two designs, one to form a 9-in. air space between the back of the refractory blocks and the face of the vertical steel columns in which the channels are attached, and

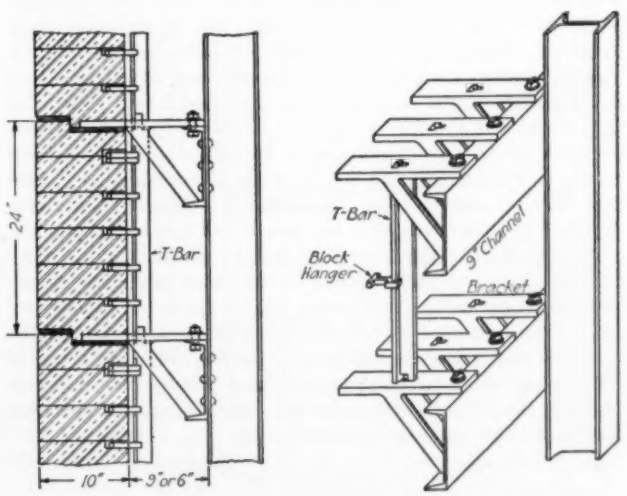

FIG. 7 CONSTRUCTION OF MCLEOD & HENRY COMPANY'S WALL

the other to form a 6-in. air space. A brick wall is laid up between the columns. The T-bar assembly is shown in the cut. The advantages claimed for this construction are its ruggedness, simplicity, and the small amount of labor required to place the refractory blocks. The blocks are laid with a small amount of high-temperature cement buttered along the edge of block on the furnace side.

The Laclede-Christy Wall

The Laclede-Christy Company installed what was probably

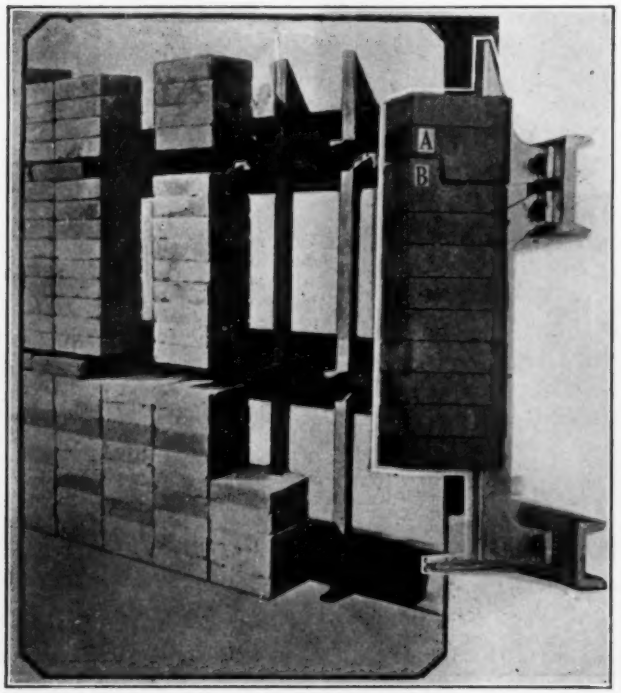

Fig. 8 Laclede-Christy Wall

the first steel-supported side-wall construction in this country in a boiler setting for the St. Joseph Lead Co., in Missouri, in 1920. This was a short curtain wall in a furnace for a 768-hp. Stirling boiler fired with pulverized coal. In this case the refractory blocks were held in alignment by steel I-beams and were supported on structural steel beams. Very little development work was then done on this side wall construction until recently. The design now offered is illustrated by Fig. 8. The wall blocks are 3 in. by $10^1/_2$ in. face and 10 in. deep, and are identical with those used in the Laclede-Christy suspended arch construction. The horizontal bands or courses between supports are of any height desired to suit the structural-steel design of the furnace up to 6 ft. high. The cast-iron hanger bars therefore vary in length from about 2 ft. 6 in. to a maximum of 6 ft. The bars are bolted at the top and bottom ends to the horizontal steel members. Two courses of sealing tile "A" and "B" as shown in the insert in Fig. 8 are laid between the sections or groups of tiles carried by the hangers. Refractory tile "A" is supported by a foot or shelf at the lower end of the cast-iron hanger and is separated from tile "B" at the top of the section below by an expansion joint filled with plastic refractory material. The blocks are laid with plastic bonding clay in the horizontal and vertical joints.

Comparison of Different Walls

Table 1, giving the comparison of the number of refractory shapes and the different kinds or forms of castings required for the different walls, is of interest. It also shows the relative weights of refractories, castings, and steelwork per square foot of wall surface. These weights do not include any outside cover plates or wall construction, and the steel weights may vary considerably, depending on the design of the furnace.

TABLE 1 COMPARISON OF CERTAIN FEATURES OF AIR-COOLED WALLS

Wall type	Number of special refractory shapes	Number of kinds of castings	Avg. weight per sq. ft. of wall: Refractory blocks, lb.	Cast iron, lb.	Supporting steel, lb.
Laclede-Christy	3	1	92	15.0	15
Detrick	3	1	100	18.0	20
American	5	3	107 (*c*)	24 (*b*)	19
De Wolf	4 (*a*)	1	120	3.0	13
Bigelow	1	1 (*a*)	103	13.4	10
McLeod & Henry	3	3	108 (*c*)	17	18

(*b*) Estimated weights.
(*c*) Based on 130 lb. per cu. ft.

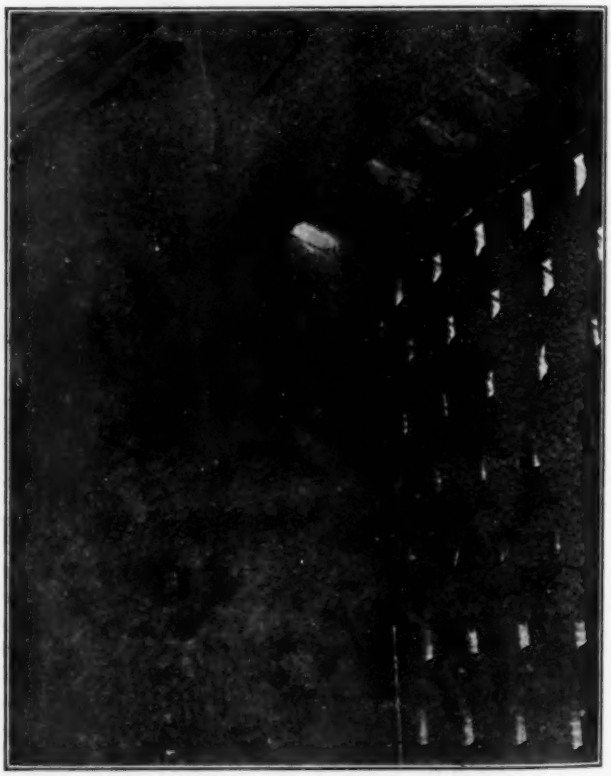

Fig. 9 Interior of Furnace for 1112-Hp. Stirling Boiler, Sioux City (Iowa) Gas and Electric Company

Of interest also is the remarkable increase in the air-cooled supported refractory wall surface installed by four of the principal manufacturers during each of the last five years:

Year	Total sq. ft. of air-cooled walls installed each year
1924	35,358
1925	44,505
1926	106,686
1927	117,289
1928	197,379

Bonded Air-Cooled Walls

Air-cooled walls are sometimes built for the smaller boiler furnaces by constructing hollow spaces or flues in the interior

of the wall and arranging for a circulation of air through the flues or ducts. This may be accomplished by using regular 9-in. standard firebrick or special refractory blocks bonded into the wall. Although this type of wall is sold by the manufacturers of the special shapes for furnaces having comparatively high walls, it is the author's belief that walls higher than 10 or 12 ft. should not be constructed in this manner. The inner lining of such a wall on the furnace side would have a greater vertical expansion than the main outer wall to which it is bonded. This would be likely to result in breaking the bond and allowing the interior lining to fall away from the outer wall.

Among the constructions of the bonded air-cooled walls the following may be mentioned:

1 *The American Arch Company* offer special air-cooled blocks which are bonded to the main wall with standard 9-in. firebrick. These blocks form horizontal and vertical air passages.

2 *The Bigelow-Liptak Company* offer a design of air-cooled refractory bonded furnace wall having a lining constructed of one course of standard firebrick which is bonded to the main wall with special bonding tile. In this construction the bonding tile will support the lining for repair work, but this supporting feature is not relied upon to carry any of the weight of the lining wall when in regular service. The bonding tile are so designed that they may readily be replaced.

3 *The Combustion Engineering Corporation* offer a design in which the furnace-lining wall is built of 9-in. standard firebrick in sections of any desired height between horizontal courses of bonding tile. The bonding tile are 5 in. thick, 9 in. wide, and 15 in. deep, laid in courses between the sections of lining wall, thus forming horizontal air passages between the lining and outer wall construction. The bonding tile are held to the outer wall by hooks which engage in holes in the bonding tile and pass through the main wall with anchor plates and nuts on the outside.

4 *The Drake Non-Clinkering Furnace Block Company*, in addition to their perforated carborundum blocks for admitting air to the furnace, also produce a carborundum air-cooled lining for furnace walls. In this construction the special wall lining blocks are of two shapes, all tongued and grooved together and held to the main outer wall by cast-iron anchors laid in the wall. These anchors support the lining laterally, but do not support the weight of the lining wall.

5 *The Furnace Economy Company* have produced special refractory blocks which, when laid in the wall in pairs, resemble two square tile attached to each other by a cylindrical section. The pairs are bonded in double courses so that the cooling air in passing through the spaces in the wall impinges upon the cylindrical surfaces and thus has greater cooling effect.

6 *The McLeod & Henry Company* supply special refractory furnace lining blocks of two designs. One design is 9 in. wide by 10 in. high by 6 in. thick, with 9 pyramidal projections 3 in. high on the back. These are laid in double courses with bonding tile hooked to the main wall to hold them in line laterally. Another design is similar to the one described in (3), having bonding tile and firebrick lining wall. In this case solid refractory blocks 10 in. in depth are substituted for the 9-in. double-course wall.

OPERATING SERVICE CONDITIONS OF AIR-COOLED WALLS

There exists a vast fund of interesting and pertinent information concerning the performance of air-cooled walls in service. But the combination of variable factors entering into the conditions of service render it a most difficult and laborious task to gather data to definitely establish facts or to set up principles which may be used in the design and operation of furnaces. The following results of operation of furnaces with air-cooled walls obtained at certain plants are presented with the hope that the information will be of interest:

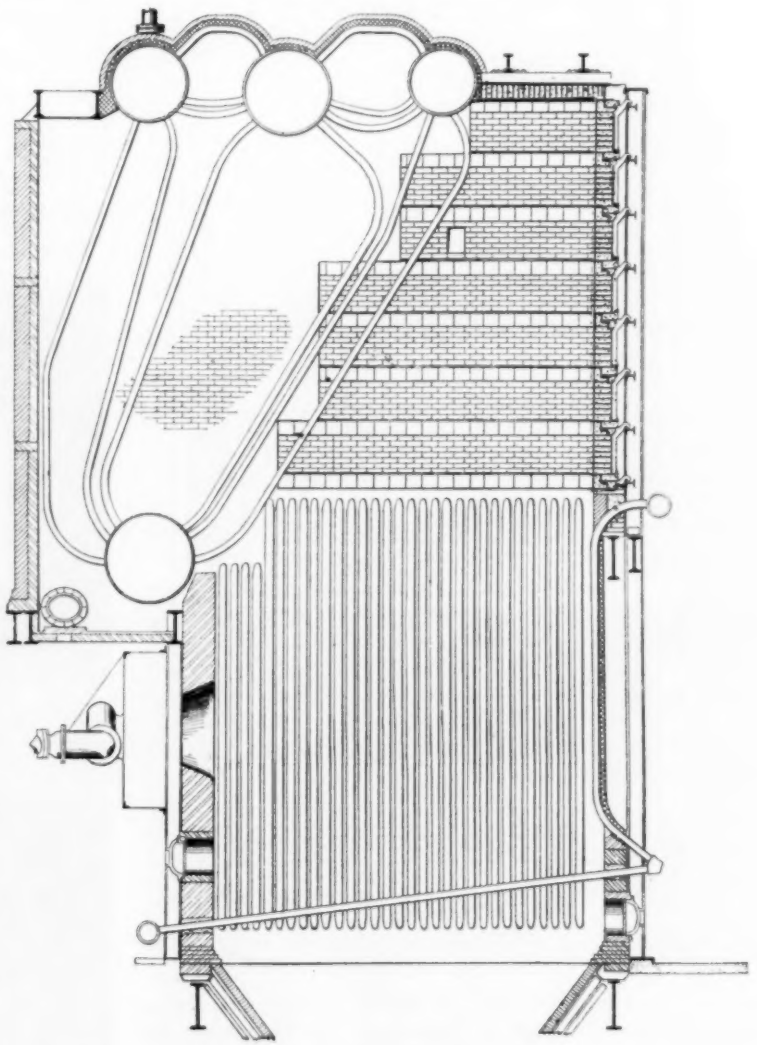

FIG. 10 SETTING FOR 2500-HP. HEINE BOILERS, GULF STATE SERVICE CORPORATION, HOLT, ALA.

THE DETRICK WALL

Detrick walls have been installed in the furnaces for many types of boilers and for average ratings of from 175 per cent to nearly 300 per cent, and for peak ratings as high as 425 per cent where no water-cooled walls were also installed. The first installation at Binghamton operates on 8-hr. peaks at 325 per cent of rating. At this plant the average rate of heat liberation is 10,750 B.t.u. per cu. ft. of furnace volume per hr.; at the higher ratings it is as high as 16,190 B.t.u. per cu. ft. per hr.

The fusion temperature of the ash is 2260 deg. fahr., and slagging of the side walls occurs if the CO_2 is over 14 per cent. No serious trouble or maintenance expense has been encountered from spalling and erosion. The air circulates horizontally around the side walls and enters through ports in the front walls in the immediate vicinity of the long pulverized-fuel flames; the temperature of the air is about 200 deg. fahr. The photo-

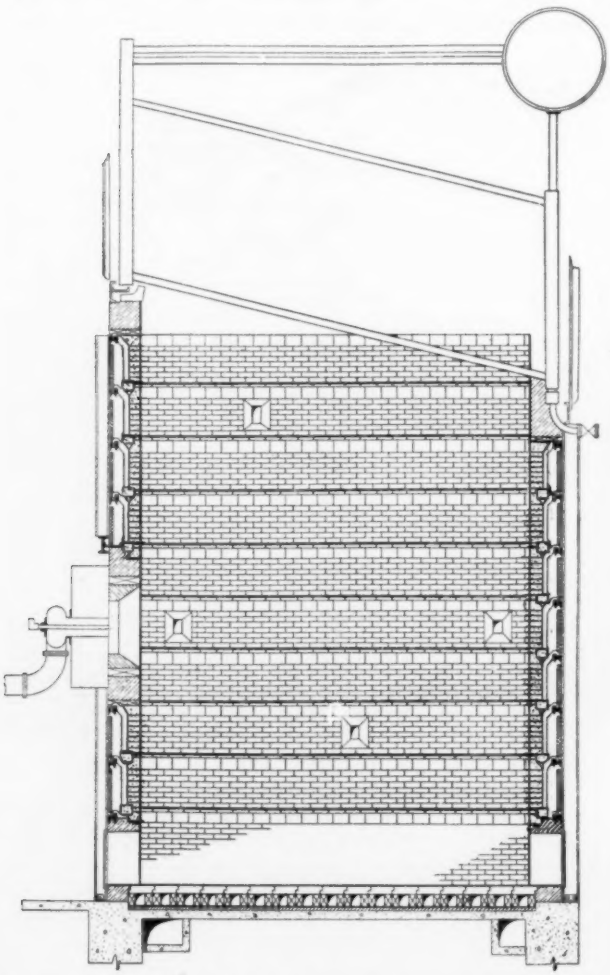

FIG. 11 SETTING FOR 614-HP. WALSH & WEIDNER BOILER, E. I. DU PONT DE NEMOURS & COMPANY, NEWBURGH, N. Y.

graph of another furnace which is reproduced in Fig. 9 was taken after a considerable period of operation, with ratings varying from an average of 200 per cent to a maximum of 350 per cent for one hour. The CO_2 content of flue gases is maintained at $13^1/_2$ per cent when operating at 200 per cent of rating and 11 per cent at 300 per cent of rating. The fuels burned in pulverized form in three boilers at the Big Sioux Station have widely varying characteristics. Table 2 gives in condensed form the proximate analysis of some of the fuels used during the past year. Practically the same amount of slagging results with the different coals, and this largely depends on the watchfulness of the operator in adjusting the amount of excess air at different ratings to prevent slagging and maintain the highest practicable CO_2 content in the furnace gases. No spalling has been experienced, but erosion of the front walls and of the side walls in the vicinity of the path of the flame has occurred. The front wall of each furnace has been repaired once since June, 1925, with replacements of refractories and castings, but the side walls have not been renewed. The outside burners have been tilted away from the side walls, additional air has been admitted through the arch between outside burners and the side walls, and repairs where necessary consisting of ganister and fireclay have been applied with a cement gun after each period of operation. Boilers have thus been kept in service for 2550 steaming hours before being taken out of service for inspection. This furnace is designed with an air-cooled ash hopper, water-cooled bridge wall, and is proportioned for a heat liberation of 18,000 B.t.u. per cu. ft. per hr. at 350 per cent of rating.

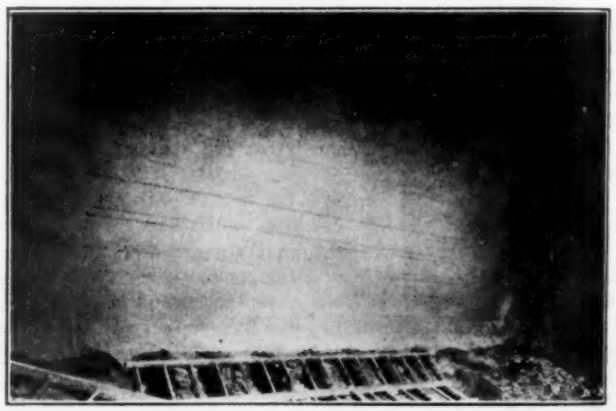

FIG. 12 INTERIOR VIEW OF BIGELOW FRONT WALL FOR 1510-HP. BABCOCK & WILCOX BOILER, EDISON ELECTRIC ILLUMINATING COMPANY, EDGAR STATION, BOSTON, MASS.

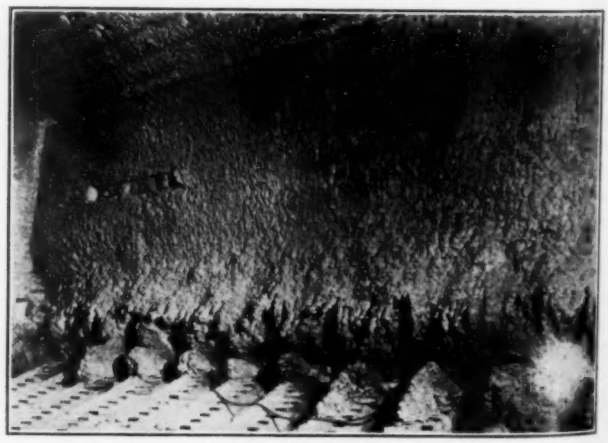

FIG. 13 INTERIOR VIEW OF SOLID-REFRACTORY FRONT WALL FOR 1510-HP. BABCOCK & WILCOX BOILER, EDISON ELECTRIC ILLUMINATING COMPANY, EDGAR STATION, BOSTON, MASS.

A study of the designs of seven of the larger installations of the Detrick wall in which less than 10 per cent of the heating surface is installed as water walls or screens indicates that the furnaces were proportioned, as to volume, for an average maxi-

mum heat liberation of 18,600 B.t.u. per hr. per cu. ft. of furnace volume.

The American Wall

Fig. 10 shows an interesting application of the American side-wall construction in the furnaces for three 2500-hp. bent-tube boilers fired with short-flame pulverized-coal burners set in the bridge wall under the mud drum. The lower portion of the furnace is designed with water-cooled walls and water screen, and the upper portions are built with air-cooled refractory walls.

Another noteworthy installation is shown in Fig. 11. This furnace-wall construction is for a 614-hp. cross-drum boiler fired with a low-velocity or short-flame pulverized-coal burner. In this case the four walls are entirely constructed with air-cooled refractory walls, and the furnace bottom is also air cooled. This furnace is designed for operation of boiler at 200 per cent average and 250 per cent maximum ratings. High furnace temperatures and slagging occur when the CO_2 in maintained at about 14.5 per cent, but slagging ceases when the excess air is increased to reduce the CO_2 to not over 13.5 per cent. When the boiler is operating at about 175 per cent of rating the air for cooling the side walls is heated to about 240 deg. fahr., and is used partly as primary air for drying

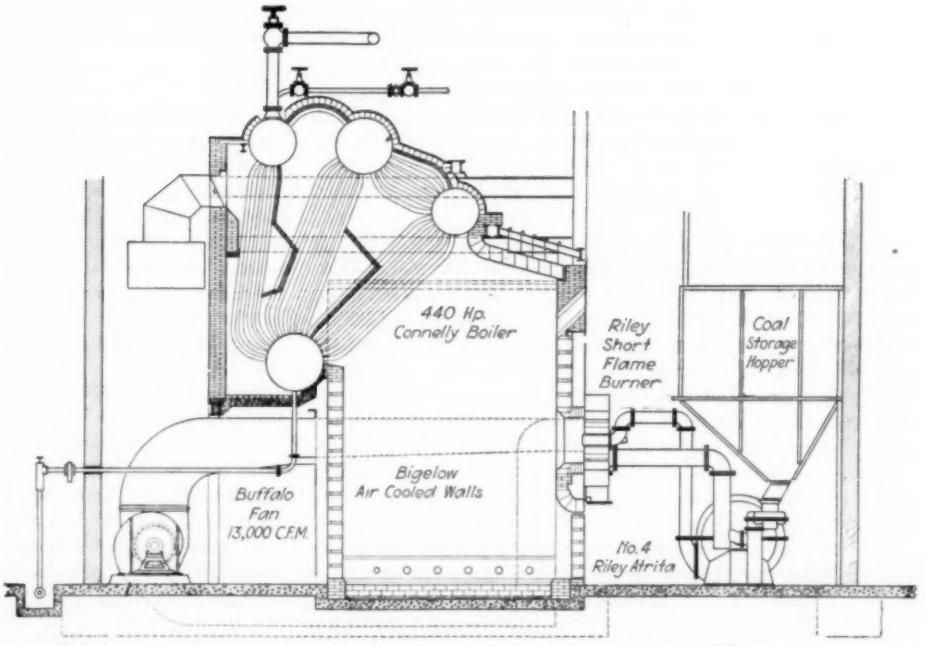

Fig. 14 Setting for 440-Hp. Connelly Boiler, General Motors of Canada, Ltd., Oshawa, Ont.

Fig. 16 Interior of Furnace for 600-Hp. Connelly Boiler, Syracuse University, Syracuse, N. Y.

and conveying the pulverized coal from the unit pulverizer and partly as secondary air admitted to the furnace through the short-flame burner. At certain times this boiler has been operated at normal rating with coal containing 10 per cent moisture as received by the unit pulverizer. The heat liberation in this furnace at 250 per cent of rating is at the rate of 13,300 B.t.u. per cu. ft. per hr.

The Bigelow Wall

A typical illustration of an installation of the Bigelow wall is shown in Fig. 12, a photograph taken after 3000 hours of service. This furnace is for a Babcock & Wilcox cross-drum boiler of 1510 boiler hp., steam pressure 1250 lb., and has been operated at 350 per cent of rating with CO_2 at about 13 per cent and air preheated to approximately 350 deg. fahr. The furnace is fired by multiple-retort stokers and is constructed with Bailey water walls on the two sides and bridge wall and a Bigelow front wall. The coal burned is New River nut and slack, taken from the Tug River and Sewall seams in West Virginia. The refractory walls coat over with a glaze of slag, and there is no trouble with erosion or spalling.

Fig. 13 shows a solid refractory wall in a furnace operating with the same fuel and rating conditions after 2600 hours of service. This furnace is identical with that shown in Fig. 12 as to dimensions and stoker equipment, but the side walls and front wall are solid refractory, not air cooled or water cooled.

This comparison shows in a marked degree the effect of air cooling and lower furnace temperature on the prevention of slag adhesion to the interior surface of furnace walls.

The author's experience with the Bigelow wall in a furnace burning both pulverized coal and kiln-dried wood chips, shavings, and sawdust may be of interest. Fig. 14 shows one of two 440-hp. Connelly boilers, each one set with furnaces fired with a low-velocity short-flame burner in the front wall and with four ports through the upper part of the front wall for admitting the wood fuel. The four side walls are of Bigelow wall construction. The air for side-wall cooling is admitted through ports at the top and bottom of the vertical air ducts in the side and rear walls, and is drawn off horizontally along the center of the walls to an air preheater. The air, preheated to a temperature of about 400 deg. fahr., is then forced either to the pulverized-coal burner or, when burning wood, through the small ports at the bottom of the furnace, where it enters at high velocity and rapidly burns any of the larger pieces of wood that do not burn in suspension.

Wood is burned during the working hours of the wood mill, the boiler operating at about 200 to 250 per cent of rating; CO_2 is maintained at between 12 and 14 per cent. At night and over week ends pulverized coal is burned, maintaining approximately the same ratings. Once in three weeks the furnace is closed down and the slag and accumulated ashes are removed from the furnace bottom which is neither air cooled nor water cooled. The wood fire is 200 to 300 deg. hotter than the coal fire, so that practically all the ash deposited as such when burning coal is soon melted into a slag after the wood fire has been maintained for some time. The combination of wood and coal ash and high furnace temperature creates a most severe condition for erosion and fluxing action on the side walls. After about two years of this service the side-wall blocks opposite the burner had eroded away about 5 in. from the original surface, and it was decided to repair the walls—for the first time. This erosion was at the rate of about 0.2 in. per month. At another plant in which similar kiln-dried wood refuse was burned at somewhat lower boiler ratings, the furnaces suffered an erosive action which carried away from 1 in. to $1^1/_4$ in. of refractory surface from the furnace walls per month. These walls were constructed of solid firebrick and were arranged so that a 9-in. lining could be frequently replaced.

The DeWolf Wall

A noteworthy installation of the DeWolf wall is that of a furnace for a Bigelow-Hornsby boiler of 1122 boiler hp. rated capacity. (Rating includes the economizer section of the heating surface.) This furnace (Fig. 15), however, is designed with tubes spaced on 18-in. centers adjacent to the interior surface of the air-cooled walls to produce sufficient cooling effect to permit operation at high ratings. The furnace is fired with pulverized coal, using high-velocity long-flame burners and has been in operation for three years, with ratings varying between 50 and 400 per cent. The photograph reproduced in Fig. 15 was taken after the furnace has been in operation for 2 years and 10 months, during which time 21,930 tons of coal had been burned.

Fig. 16 illustrates another furnace constructed with the DeWolf wall which had been operating 9 months when the photograph was taken, at ratings between 50 and 325 per cent. The walls are said to be free from cracks and in excellent condition. This furnace is for a 600-hp. Connelly boiler, fired with pulverized coal, and is not provided with water-tube cooling along the face of the walls.

GENERAL CONCLUSIONS

In selecting a type of wall for boiler furnaces the engineer should consider the service requirements of the boiler, the type of equipment selected for burning the fuel, and the economics of the plant operation, including fixed charges on the investment.

If the furnace is to be stoker fired and is to be designed for a moderate maximum heat liberation of not more than 25,000 B.t.u. per cu. ft. of furnace volume per hour, air-cooled walls should prove quite satisfactory. If the maximum heat liberation is greater than 25,000 B.t.u. per cu. ft. per hour, then water-cooled bridge walls should be considered and a certain amount of water cooling of the side walls, depending on the maximum rate of combustion. The air after passing through the side-wall cooling ducts should be returned to furnace for combustion, thus reducing the radiation losses.

When pulverized coal, natural gas, fuel oil, or kiln-dried wood refuse is to be burned, the problem is somewhat different. Lower rates of heat liberation per cubic foot of furnace, the length and form of the flame, the load factor of the boiler, the fusion temperature of the ash, and the design of the boiler with respect to the extent and position of radiant heating surface exposed to the furnace should be carefully studied. The furnace walls should have little, if any, water-cooling surface if the load factor is low and the boiler must be operated at times at low ratings. On the other hand, if a high load factor is possible and the boiler will at all times be operated at high ratings, more water cooling of the side walls is justified. In general the furnace for rates of heat liberation of less than 15,000 B.t.u. per cu. ft. per hr. may be constructed with air-cooled side walls and ash hoppers, provided the furnace bottom is sufficiently depressed below the flame travel to prevent slagging of the ash. If the rate of heat liberation is between 15,000 and 20,000 B.t.u. per cu. ft. per hr. a water screen in the furnace bottom and a certain amount of water cooling of one or more of the side walls is advisable. If the rate of combustion liberates more than 20,000 B.t.u. per cu. ft. per hr., a still greater amount of radiant heating surface in the side walls is necessary.

Furnace constructed with air-cooled walls, especially if without water-cooling protection, should be so designed that there will be no impingement of the flame upon the wall, thus preventing erosion.

It is the author's belief that when a careful study of all the economic factors of construction and operating costs of both air-cooled and water-cooled furnace walls has been made the saving in fixed charges and in loss of carbon in the ash refuse in the case of furnaces with air-cooled refractory walls is greater than the saving in wall maintenance and in the loss of heat through excess air in the case of furnaces with water-cooled walls. Present engineering practice indicates that there is a distinct field for air-cooled supported side-wall construction and another field for water-cooled side-wall construction, and that in many cases combinations of the two types of construction may be used to advantage.

Discussion

W. A. Shoudy.[2] Mr. Gladden has presented a very complete survey of the air-cooled walls that are available in this country. The impartial way in which he has presented the various types of walls will make the paper of considerable value to the designer of boiler houses. He has also pointed out the important fact that the decision to use either water-cooled or air-cooled furnace walls must be made upon an economic rather than a technical basis.

It is unfortunate that Mr. Gladden has used the term "per cent rating" in the discussion of boiler furnaces. Unless the type of boiler is specified, the use of this term may lead to wrong conclusions in furnace design. The writer believes that any just comparison of furnace operation should be in B.t.u. per cubic foot per hour or a similar unit.

It is very interesting to note the rather wide use of air-cooled walls, and particularly the very rapid development, as shown in the data on the sixth page. It is evidence of the fact that the water-cooled wall has not replaced the refractory, but rather has stimulated its development, and we now find that there is a field for each type of furnace. There is no sharp line of demarcation between the two fields, but in general the field of the water-cooled furnace is that of the high-capacity, high-load-factor installation, and that of the refractory furnace, lower capacities. It might be better to substitute for the term "capacity" high-B.t.u. liberation. We have several installations of high-steam-capacity units using air-cooled walls, some of them delivering as high as 300,000 lb. of steam per hour, but these installations operate with B.t.u. releases of 20,000 B.t.u. per cu. ft. per hour and under. The same steaming capacities can be obtained with refractory walls as with water walls; consequently the decision must be based on a comparison of the total cost of the installation and a determination as to whether the increased fixed charges due to the more expensive water walls are not greater than the slightly higher maintenance cost of the refractory wall.

There have not yet been sufficient data collected to determine definitely the limitations of the air-cooled wall. During the past two years the writer has been investigating substantially all of the furnaces installed by one manufacturer. Operating records are not always fully reliable; consequently, only 15 installations totaling 48 boilers could be selected as truly representing air-cooled furnace wall practice. The principal data concerning these installations is given in Table 3 and covers boilers which have been operating as many as 17,000 hours and others which have consumed over 500,000 tons of coal.

The most satisfactory basis of comparison seems to be that of the cost of repairs expressed in cents per ton of coal burned. These costs vary from nothing to nearly five cents. The majority, however, show less than two cents per ton. The B.t.u. release per cubic foot is given as maximum and average. The term "maximum" is not fully satisfactory, because in some cases it applies only to extremely short peaks, whereas in others it represents regularly recurring high peaks.

The results, however, indicate that in general the air-cooled wall can be used for B.t.u. releases as high as 20,000 and that with a small area of water-cooled wall 25,000 B.t.u. per cu. ft. per hour is not out of reason. Before the B.t.u. releases can be determined, however, full knowledge of the character of the fuel must be obtained.

The fusing temperature of the ash determines the limitation of the correctly designed air-cooled sectionally supported walls; that is, the fluxing action of the ash on the refractory determines its life. An ash that fuses below 2100 deg. fahr. will cause trouble with any refractory wall unless burned with about 40 per cent excess air. Air cooling alone will not suffice. When size of unit or load factor will not warrant the high cost of water-cooled walls and low excess air is necessary, partial water cooling such as a bridge wall or side wall will give a very satisfactory compromise.

The evils of high excess air or low CO_2 have been overemphasized. There is an optimum per cent excess air that varies with each installation. Smoke may be one limitation. It is obviously illogical to design a furnace for low excess air if it cannot be obtained without smoke. In such cases the air-cooled wall is fully as satisfactory and much cheaper than the water wall, and in some cases to be preferred, because combustion is improved by the hot walls.

When a boiler is used without economizer or air heater, an increase in excess air results in a lower efficiency because of the higher exit-gas temperature, but with economizers or air heaters the reduction in efficiency is negligible, for the following reasons:

An increase in excess air lowers furnace temperature, thus reducing absorption by radiation, and the transfer from the gas by convection is reduced because of the lower temperature difference between water and gas. This results in a high exit-gas temperature, but on entering the economizer the heat transfer by the economizer is increased because of the greater temperature difference and the greater velocity of gas due to the increase in gas volume.

Consequently, an increase of the per cent in excess air of from 30 to 40 per cent results in so small a difference in final exit-gas temperature that it is negligible. The gas weight has increased about seven per cent and the stack loss about seven per cent of 10 or 11 per cent, or the efficiency has been reduced about nine-tenths of one per cent. However, this loss sometimes is an actual gain because the increase in air for combustion may eliminate all loss from CO or reduce carbon losses to the stack.

The air-cooled wall to be satisfactory must meet certain definite conditions. Every refractory wall is air-cooled, but the built-up wall is so thick that the cooling action is negligible. To obtain any cooling effect at all, the wall must be relatively thin. Nine or ten inches is probably the maximum thickness with which air cooling is effective, and seven or eight inches is as thin as it can be made without weakening the construction. Too thin a wall will not be sufficiently gas-tight.

A refractory wall fails for one of five reasons: by melting, softening, spalling, fluxing, or expansion. Melting and spalling can be corrected by the selection of the refractory. Fluxing is a function of ash-fusing temperature and furnace temperature and can be controlled. Softening removes the support from the upper rows of brick, causing the wall to fall into the furnace. Expansion develops bad cracks. If the lower course of brick can be relieved from the weight of the wall, slight softening will not be serious. This has been one reason for the success of the sectionally supported wall. There is never more than 30 in. of brick above any tile.

[2] Associate Professor of Mechanical Engineering, Columbia University, New York, N. Y. Mem. A.S.M.E.

If the refractory is so supported that there may be slight movements due to expansion, serious cracks will not develop. The sectionally supported wall being in such short sections makes it possible for a tile to move under the change in temperature. This relief of expansion strains prevents the formation of cracks.

If these few fundamentals are borne in mind in the selection or design of an air-cooled wall, the cost of maintenance will be almost negligible. One of the reasons for the trend toward the limitation of the use of the refractory has been the fact that these principles have been lost sight of. Improperly designed walls have failed, and the entire class of wall has been condemned with the improperly designed ones.

TABLE 3 MAINTENANCE RECORD OF 48 BOILERS USING PULVERIZED COAL, DETRICK FURNACES, AS OF JULY 1, 1926

Plant	Operating hours, average per boiler	Total tons of coal burned all boilers	Fusing temperature of ash	Per cent of excess air	B.t.u. release per cu. ft. Maximum	B.t.u. release per cu. ft. Average	Water cooling in per cent of boiler surface	Total cost of repairs in cents per ton of coal fired

[a] Months. [b] Superheater.

R. J. GAUDY.[3] Mr. Gladden has produced on this subject exactly what is needed in this and many other engineering items. In this paper the development, history and physical comparisons, and operating experience are brought together in a complete manner.

No engineer can be an exponent of water walls or air walls, as the elements of analysis, as well stated by Mr. Gladden, will positively control the selection based upon true economy.

In Mr. Gladden's conclusion he has set forth several dividing lines of release on satisfactory service. These are very valuable figures, as in checking several installations, installed by us and by others, the satisfaction in each case falls upon the side of the demarcation established by Mr. Gladden's findings and experience.

A series of articles edited in exactly the way this paper was written and covering various equipments and materials would produce a reference work of inestimable value.

G. G. HOLLINS.[4] It is essential to design the supporting steelwork in these walls so that it can expand freely and uniformly and not cause distortion. The designs of the walls should be scrutinized very carefully to see that the steelwork will not be warped by unequal heating.

It takes a relatively small temperature difference between the two flanges of an I-beam to cause considerable bowing of the beam if of any length. For instance, in the case of a beam 20 ft. long a temperature difference of 20 deg. per inch depth will cause the beam to bow in the center approximately one inch, and if the beam is 30 ft. long the bowing will be approximately two inches. The bowing of the beam of course will be toward the hot side. It is suggested that steel members of any length be of ample cross-section so as to permit free flow of the heat and equalizing of the temperature, and that the air circulation be directed so as to obtain as nearly as possible uniform cooling of the steel.

OLLISON CRAIG.[5] The heat release per cubic foot should depend not only on the type of furnace—that is, whether solid refractory wall, air-cooled structurally supported wall, or wholly or partially water-cooled wall—but also should depend on the fusion temperature of the ash of the coal to be burned.

In the March, 1928, issue of *Mechanical Engineering* there was published a tabulation by H. W. Brooks citing figures for heat releases under various conditions of character of wall and fusion temperature of ash. It is impossible to fix on a definite numerical value for a particular case. This tabulation, however, sets up a very good set of averages and makes an excellent guide to use in practical design. It is quite possible to depart considerably from these figures without radical changes in results, and the figures in the tabulation should be considered as indications only.

Less heat release per cubic foot simply means a larger furnace volume for a given rate of fuel burning. We can imagine that at a given rate of fuel burning with given fuel-burning equipment, a certain flame having a certain outline will be formed. It is probable that a larger furnace for a given rate of fuel burning is for the purpose of having the furnace walls at a greater distance from the surface of the flame. It would seem apparent that the lower the fusion temperature of the ash, the greater this distance should be, and that the refractory surface should be at a greater distance than the water-cooled surface.

In choosing between air-cooled structurally supported walls and partially or wholly water-cooled walls the decision should be based on a number of factors, but one factor which should receive considerable weight is that of load factor. The less the load factor the less money that can be spent for protecting the wall by water cooling. If the load factor is low it will be found more economical to spend money in the form of coal during the short periods of peak loads rather than in the form of fixed charges for water-wall construction. In the first case the charge is only during the period of peak loads, whereas in the second case the charge is continuous. It would be advisable in any given case to make a set-up of costs in order to determine which would be the most economical.

H. E. JOHNSON.[6] Referring to Mr. Shelby's suggestion that the depth of tile in an air-cooled wall could be made somewhat less, it may be of interest to know that in a construction having heavy iron brackets or radiating ribs, the most efficient depth of the tile shape is probably about four inches. This refers to heat conduction and absence of slag. There have been a number of Laclede-Christy arches on which the tile burned down to within two or three inches of the iron work, and the arch performance was very satisfactory in that condition. However, as an added factor of safety for such emergencies as tile breakage and other mechanical contingencies, it is found practical to make the tile deeper.

One of the points which is often overlooked in determining the practicability of installing air-cooled walls is the fact that they can be repaired more rapidly and easily than the straight refractory walls. In these days when production is worth so much, and plants are designed to run at the greatest capacity for the capital invested, shutdowns are costly. When every hour that the boiler is off the line costs money, a few hours or a day saved in repairs may effect an economy which is more than might be surmised at first thought.

Author's Closure

Referring to Professor Shoudy's discussion, the author appreciates the necessity of adhering to consistent and proper terms in connection with boiler-plant design and operation. The various terms relating to boiler capacities do not necessarily relate to furnace performance, except that perhaps the per cent of rating is commonly understood by average boiler operators to give a relative idea of the capacity performance of the boiler. If this factor is high, then the furnace must be liberating more heat than if this factor is low. The boiler and the furnace are necessarily two parts of a common unit, and the furnace may be large or small relative to the capacity of the boiler for which it is furnishing the heat. Professor Shoudy is correct that the terms relating to capacity performance in the discussion of boiler furnaces should be confined to the rate of heat liberation per cubic foot of furnace volume per hour. This factor again is only relative as affecting the service required of the refractories used in the furnace walls as the heat absorbed by the walls will vary due to the proximity of the inner surfaces of the walls to the flame; or to the reflected heat from opposite walls, if the furnace be narrow; or to the cooling effect of radiant-heat-absorbing surfaces in the boiler or furnace. However, this term is undoubtedly as good a unit of furnace operating capacity as can be used for general consideration of the design and operation of boiler furnaces.

Table 3, given in Professor Shoudy's discussion, contains valuable information concerning the maintenance cost of the furnaces in which there is no water-cooling surface as compared with furnaces that also have water-cooling surfaces. The author has compared the five furnaces given in Professor Shoudy's tabulation in which no water cooling is installed in connection with the air-cooled walls, with the ten furnaces in which the per cent of water cooling in the furnace walls ranges from 2.6 per cent to 14.9 per cent of that in the boiler-heating surface. It is found that the maintenance cost per ton of coal fired in furnaces without water-cooling protection averages 1.67 cents per ton of coal fired, while the average maintenance cost for the group of air-cooled furnaces in which water-cooling protection is also provided is 74 cents per ton of coal fired. Whether this saving in maintenance cost by providing water-cooling protection is offset by the additional fixed charges of the cost of providing this surface in the furnace, is a matter of economic study. It is appreciated that the fusing temperature of the ash and the labor cost of removing the ashes from the bottom of the furnace also enter into the justification for the installation of water screens.

Professor Shoudy's data, given in Table 3, furnish the following data with regard to average operating practice in the rate of heat liberation in furnaces constructed with air-cooled refractory walls:

	B.t.u. liberation per cu. ft. Average of maximum	Average of normals
Five plants in which air-cooled furnace walls are not provided with water-cooling surface	19,400	12,570
Ten plants in which water-cooling surface is installed in the furnaces of air-cooled refractory wall construction	19,810	14,440

Table 4 lists 15 plants in which a similar segregation of furnaces with air-cooled walls has been made, nine plants having no water cooling whatever, and six being provided with radiant-heat-absorbent surfaces in the side walls, or with water screens, or both. It should be noted that each furnace in the latter group is installed in a public-utility plant and is evidence of the conservative values of heat release per cubic foot of volume that are used by public-utility engineers.

Professor Shoudy points out that the use of economizers or air preheaters eliminates to a certain extent the desirability of maintaining as small a percentage of excess air as possible. With this equipment in connection with the boiler setting having air-cooled furnace-wall construction, the operator may control the slagging and erosion of the furnace walls with greater ease than if this equipment is not present. As Professor Shoudy has indicated, the following advantages of supported air-cooled refractory-wall construction may be cited; the low maintenance cost compared with fixed charges of a smaller furnace constructed with water-cooled walls, the ease of making rapairs, and the elimination of difficulties from sagging walls due to softening or spalling of the firebrick.

Referring to Mr. Craig's discussion, the author realizes the influence that the fusing temperature of the ash should have on the furnace design. The choice between structurally supported air-cooled walls and water-cooled walls, or the extent of water-cooling protection for refractory walls, depends not only on the economic features of the installation, but also on the minimum rating at which the furnace may have to operate. It is the author's belief that a lower minimum heat release per cubic foot of furnace volume may be obtained with refractory walls than with water-cooled walls in any given setting.

The factors of heat release published by H. W. Brooks (*Mechanical Engineering*, March, 1928), as cited by Mr. Craig in his discussion of this paper, are of real practical value to the designing engineer. These values agree quite closely with the operating practice of many of the plants cited in Professor Shoudy's discussion (Table 3) and with the data given in Table 4.

As has been pointed out in the discussion, wherever possible the natural circulation of air through the channels of air-cooled walls should be utilized. That is, for vertical baffling of the air channels the heated air should be taken off at the top of the air-cooled section rather than at the bottom to insure complete circulation past all portions of the air-cooled wall surfaces. The heated air, if not recovered, and used for combustion purposes, will result in an appreciable loss in furnace efficiency, and should therefore be utilized wherever possible.

TABLE 4 HEAT LIBERATION OF CERTAIN BOILER FURNACES

FSP-51-41

Surface Heat Transmission

By R. H. HEILMAN,[1] PITTSBURGH, PA.

In view of the dearth of reliable data on the emissivity coefficients of various surfaces at the lower temperatures met with in refrigeration and heat-insulation work, the author undertook an investigation of the subject at Mellon Institute of Industrial Research, Pittsburgh. The paper describes that investigation, and among other things gives particulars regarding the methods employed in determining surface coefficients; the radiometer used; the determination of emissivity coefficients; derivation of an equation for convection; convection losses from various geometrical shapes; total heat loss from various shapes and surfaces, etc. Several charts are included in the paper which make it possible for the engineer readily to determine the total heat loss from various surfaces, and which eliminate all need for calculations for surface temperatures up to 700 deg. fahr.

A CAREFUL perusal of the existing literature indicates that there are few reliable data on the emissivity coefficients of various surfaces at the lower temperatures met with in refrigeration and heat-insulation work. However, a careful study has been made at Mellon Institute on the total transfer of heat from bare pipes. In this investigation the total surface transfer obtained from the experiments on the bare pipes has been separated into its two components, radiation and convection.

Tests have also been conducted on circular disks and on a long, thin ribbon in a vertical position. Knowing the relative amounts of radiation and convection from these various shapes, it is possible to derive formulas which will give the heat loss by convection as a function of geometrical shape, position, temperature excess, etc. Having these formulas for convection from the various shapes, we can then determine accurately the total heat loss from any shape and for any type or nature of surface by adding to the convection loss the loss due to radiation from the well-known Stefan-Boltzmann law, and the emissivity of the various surfaces experimentally determined.

Method Used in Determining Surface Coefficients

The method used in this investigation to determine the emissivity factors for various surfaces is somewhat similar to the method used by Shakespear[2] in determining the black-body radiation constant.

The total rate of heat loss was measured under given temperature conditions for a lampblack-covered brass disk, heavily silver plated, containing an electric heating element, and later under the same conditions, except that the disk surface was highly polished. The difference between these two measurements gives the difference in radiation for lampblack and polished silver surfaces, since the convection is independent of the nature of the surface. At the same time the power measurements were taken, the ratio of radiation from the lampblack surface to that of the highly polished silvered surface was obtained from the deflections of a sensitive radiometer. Having the difference in radiation from the power measurements and the ratio of the two radiations from the radiometer, we can solve for the absolute value of each.

At the same time we can calibrate the radiometer so that we can determine directly from the radiometer readings the actual losses by radiation from any surface to which the radiometer is exposed. This method of procedure allows us not only to determine the radiation loss or radiation coefficient from various surfaces, but enables us also to measure the amount of heat lost from the same surface by convection, so that we can accurately determine the convection losses for various surfaces as functions of temperature, geometrical shape, and position.

Description of Radiometer

The radiometers usually employed by physicists generally require considerable extra equipment when they are to be used for determining radiation over a considerable temperature range.

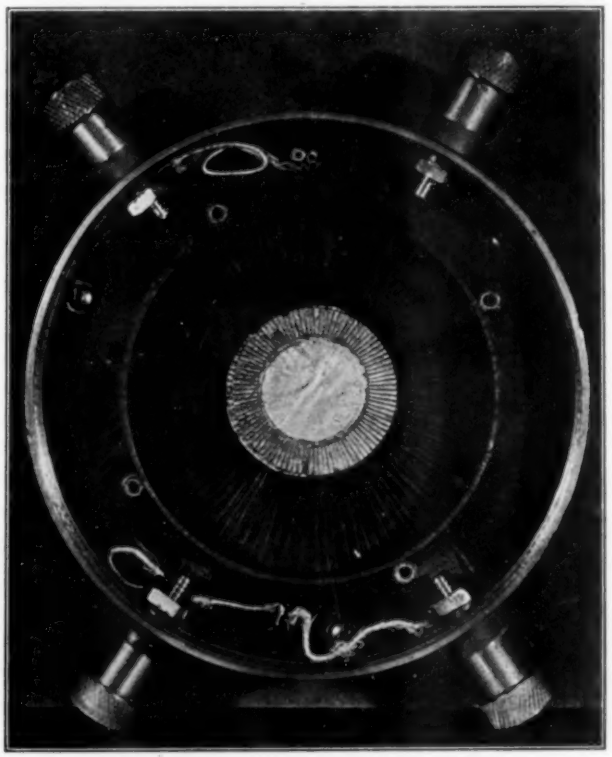

Fig. 1 Rear of Receiver

In order to keep the deflections of the galvanometer usually employed on the scale, it is necessary to employ various devices, such as varying the distance of the radiometer from the radiation source, the use of shunts in the galvanometer circuit, or the employment of sectored disks to cut down the radiation, etc.

To eliminate these devices which have a tendency to cut down the accuracy of the measurements, the author has constructed a sensitive thermopile which can be used directly on a Leeds & Northrup Type K potentiometer, which latter is sensitive enough to give direct readings at temperatures below 100 deg. fahr. and to as high a temperature as is desired.

A full-size photograph of the rear side of the receiver is shown in Fig. 1, while the complete thermopile in its mounting with the radiation disk is shown in Fig. 2.

The receiver contains 96 thermojunctions of copper and con-

---

stantan wire, No. 44 B. & S. gage copper and No. 40 B. & S. gage constantan. The receiving disk consists of a sheet of tin approximately $^7/_8$ in. in diameter and 0.0005 in. thick, to the back of which is cemented with very thin shellac, 96 copper segments approximately 0.024 sq. in. in area and 0.0003 in. thick. The hot junctions were soldered to the copper segments with a very small, specially constructed soldering iron, the amount of solder deposited on each segment being extremely minute. The cold junctions were soldered to small brass pins contained in a circular micarta holder. In constructing this receiver the lightest materials obtainable were used in order to keep down the heat capacity. The copper to which the hot junctions were soldered was obtained by electrolytically depositing a very thin film of

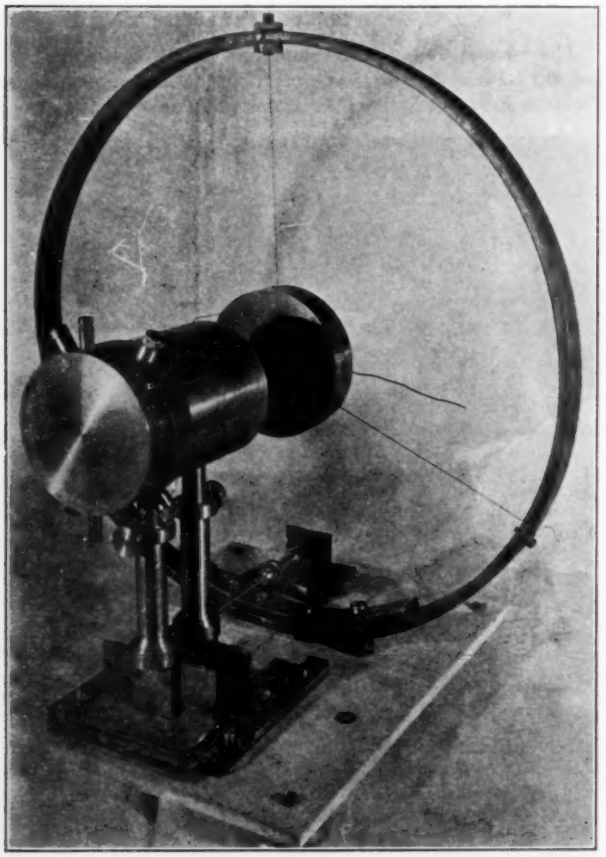

FIG. 2 THERMOPILE USED IN THE INVESTIGATION

copper on an aluminum sheet, after which the copper was stripped from the aluminum sheet.

The front side of the receiver was coated with a thin film of electrolytically precipitated platinum black, which produces a receiving surface having a very low reflection coefficient and a very high absorption coefficient.

When this receiver is placed at a distance of 3.75 in. from a radiation source of lampblack at a temperature of 300 deg. fahr., the e.m.f. generated by the receiver amounts to 5400 microvolts.

A copper-constantan thermocouple is soldered to one of the cold-junction pins, which enables one to determine at any time the temperature of the receiving disk.

DETERMINATION OF EMISSIVITY COEFFICIENTS

As mentioned previously, the method used in this investigation was to measure the total heat dissipated by two surfaces at the same temperature and also to determine the ratio of the radiations emitted from the surfaces. The theory of the determinations is somewhat as follows:

Let the radiator be lampblacked and maintained at temperature T_1 deg. abs.

If we expose this surface to the radiometer, the receiving surface of which consists of a platinum-blacked disk at temperature T_2 deg. abs., we shall get a certain deflection D_1.

Let R_{B1} be the energy radiated per hour from a unit area of the blackened radiator at temperature T_1 when exposed to the blackened cold surface of the receiver at temperature T_2, and let R_{B2} be the energy radiated per hour from a unit area of the blackened receiver at temperature T_2 to the hot blackened radiator at temperature T_1. Then $D_1 = M(R_{B1} - R_{B2})$, where M is a constant.

Now let the lampblack be removed from the radiator and let the surface of the radiator be polished, raised to temperature T_1, and exposed, as before, to the radiometer. Let the deflection be D_2. Then if R_{P1} be the energy radiated per hour from a unit area of the polished surface at T_1 to the blackened receiver at T_2,

$$D_2 = M(R_{P1} - R_{P2})$$

hence

$$\frac{D_1}{D_2} = \frac{R_{B1} - R_{B2}}{R_{P1} - R_{P2}}$$

Let

$$\frac{D_1}{D_2} = K$$

then

$$\frac{K-1}{K} = \frac{(R_{B1} - R_{B2}) - (R_{P1} - R_{P2})}{R_{B1} - R_{B2}}$$

Now, let C represent the combined conduction and convection losses per hour from the blackened radiator at temperature T_1, and H_{B1} the total loss of energy per hour from the blackened radiator at temperature T_1; then

$$H_{B1} = C + A(R_{B1} - R_{B2})(1 - b)$$

where A is the area of the radiating surface of the radiator and b is the reflection coefficient of the cold receiver.

In this case the factor $(1 - b)$ is almost negligible, as the reflection factor for platinum black is approximately 0.025 and the area of the receiver is very small in comparison with the area of the radiator. Test readings also confirm this assumption, as practically no change in temperature of the radiator could be detected when the radiometer was placed in front of the radiator.

Similarly, when the lampblack is removed and the radiator polished,

$$H_{P1} = C + A(R_{P1} - R_{P2})(1 - b).$$

Let

$$H_{B1} - H_{P1} = E$$

then

$$E = (1 - b)A\{(R_{B1} - R_{B2}) - (R_{P1} - R_{P2})\}$$

$$= (1 - b)A\frac{K-1}{K}(R_{B1} - R_{B2})$$

Let

$$(R_{B1} - R_{B2}) = a(T_1^4 - T_2^4)$$

then

$$E = (1 - b)A\frac{K-1}{K}a(T_1^4 - T_2^4)$$

so that

$$a = \frac{K}{K-1} \times \frac{E}{(1 - b)A(T_1^4 - T_2^4)} \quad \text{[1]}$$

The use of lampblack on the radiator presents various difficulties in determining the constants of the radiometer. It is usually assumed by various investigators that the emissivity coefficient of a lampblack surface is approximately 98 per cent of that of a black body. However, it has been found during the course of this investigation that the emissivity of a lampblack surface varies considerably from 98 per cent of black-body radiation, especially when the lampblack is deposited over a polished silver surface. Values as low as 70 per cent and upward to 96 per cent have been obtained, depending upon the thickness of the lampblack deposited. In the first experiment it was found that the emissivity coefficient of the lampblack surface was approximately 70 per cent of black-body radiation, although the appearance of the surface indicated that the radiator was absolutely black as far as the reflection of light could be observed. It was reasoned that so low an emissivity coefficient must indicate that the thickness of the lampblack was not sufficient. The actual thickness of the lampblack on the radiator was then measured with a microscope and found to be approximately 15 microns. The radiator was then resooted with a deposit of soot from natural gas bubbled through benzene. The thickness of the lampblack deposited was measured with the microscope and found to be approximately 72 microns or approximately 0.0028 in. It was to be expected that a thickness of 0.0028 in. of lampblack, which has a very low thermal conductivity, would cause a drop in temperature between the surface of the plate and the surface of the lampblack. In order to be able to calculate the temperature drop through the lampblack, it was necessary to know the conductivity of the lampblack used. The density of the lampblack deposited was carefully determined in order that conductivity tests could be run on lampblack having approximately the same density as that on the radiator. However, it was found that the density of the lampblack deposited was considerably lower than that of any lampblack available.

Two conductivity tests were run on lampblack. In the first test the lampblack had an apparent density of 0.343 gram per cu. cm. The lampblack was then fluffed as much as possible and a second test conducted with an apparent density of 0.263 gram per cu. cm. The apparent density of the lampblack removed from the radiator was 0.0311 gram per cu. cm. While the density of the two samples tested was considerably higher than that on the receiver, an inspection of Fig. 3 indicates that there is little difference in the two samples tested, and that the true conductivity of the lampblack removed from the receiver is probably slightly lower than that indicated by the lower curve.

The calculated temperature drop through the 0.0028-in. deposit of lampblack on the radiator, when the metal is at a temperature of 500 deg. fahr., is approximately 19 deg. fahr.

This value is somewhat surprising, as it has usually been considered by various investigators that the drop through the lampblack is negligible. However, there is no question that such a drop does exist, and it is very necessary to take it into account in order to obtain accurate results. It has been found that 40–50 microns thickness of lampblack is required on a polished metal surface to give an emissivity coefficient approaching that of a black body.

It is very desirable when calibrating the instrument to calibrate it from surfaces having as high emissivity values as possible for the one surface and as low as possible for the other surface, and also to be able to determine the constants of the radiometer over the entire temperature range through which it is to be used. It has been found during the course of this investigation that the radiation from the surface of asbestos paper approaches very nearly that of a black body. The main objection to the use of asbestos paper is that the temperature range of the instrument cannot be carried as far as with lampblack. However, it is believed by the author that for lower-temperature work a thin sheet of asbestos paper can be used directly to calibrate a radiometer. For the benefit of future investigators who may wish to conduct radiation experiments, the emissivity factors as obtained during this investigation are given for asbestos paper for temperature ranges of 100 to 700 deg. fahr.

It has been found that there are a great many materials used in engineering practice which have emissivity values very close to 98 per cent of black-body radiation, and it is believed that a great many of these surfaces could be used as standard radiators in preference to lampblack, which has been used almost entirely by former investigators.

The emissivity values for asbestos paper were determined in the same manner as those for lampblack, with the exception that the actual surface temperature of the asbestos paper, which was approximately 0.015 in. thick, was measured with a No. 40 B. & S. gage copper-constantan thermocouple fastened to the asbestos surface with a thin strip of asbestos-paper tape. In this case, as also in the case of the lampblack, the increased area due to the thickness of the paper was corrected for in making the final calculations.

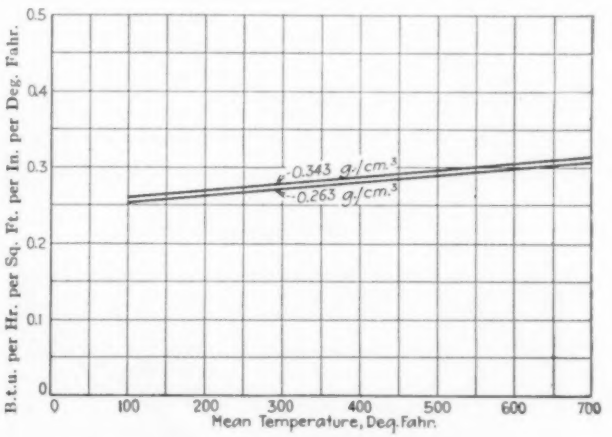

FIG. 3 THERMAL CONDUCTIVITY OF LAMPBLACK

The emissivity values obtained for various surfaces, and the approximate values for 0.0028-in. thickness of lampblack on a polished surface are shown in Table 1.

TABLE 1 EMISSIVITY VALUES FOR VARIOUS SURFACES

Surface	Temperature, deg. fahr. 100	200	300	400	500	600	700
Polished silver	0.0221	0.0252	0.0292	0.0315	0.0295	0.0308	0.0312
Lampblack	0.945	0.945	0.945	0.945	0.945	0.945	0.945
Asbestos paper	0.930	0.934	0.943	0.955	0.929	0.938	0.943
Rough steel plate	0.945	0.950	0.955	0.961	0.969	0.975	0.975
Aluminum-surfaced roofing	0.216	....	....	....	....	....	....
Polished brass	0.096	0.096	0.098	0.098	0.096	0.096	....
Flat black lacquer	0.96	0.98	....	....	....	....	....
Black lacquer	0.80	0.95	....	....	....	....	....
White lacquer	0.80	0.95	....	....	....	....	....

The following calculations show how the emissivity values of Table 1 were obtained. The data used in these calculations are taken from those obtained with the radiator surface at 300 deg. fahr. Power corrections have been made for slight changes in room temperature and for losses due to exposed power leads and supports.

CALCULATIONS FOR ASBESTOS PAPER AND POLISHED SILVER

Temperature of receiver, 80.75 deg. fahr.
Area of radiator, 0.1885 sq. ft.
Deflection by asbestos surface, 5200 microvolts

Deflection by silver surface, 139 microvolts
$K = 37.4$
Energy required to maintain asbestos surface at 300 deg., 39.7 watts, corrected for area
Energy required to maintain silver surface at 300 deg., 18.16 watts
Ratio of receiver area to exposed area of radiator, 0.117.

Then

$$a = \frac{1.027 \times 21.54 \times 3.415}{0.1885(760^4 - 540.75^4)0.997}$$

$$= 16.22 \times 10^{-10} \text{ B.t.u. per sq. ft. per hr.}$$

The black-body radiation according to the latest determinations is $17.23 \times 10^{-10} (T_1^4 - T_2^4)$ B.t.u. per sq. ft. per hr.

The emissivity e of the asbestos surface, therefore, has the value $16.22/17.23 = 0.943$. Radiation from the asbestos surface is $16.22 \times 10^{-10} \times 24.81 \times 10^{10} = 402.5$ B.t.u. per sq. ft. per hr.

Radiation and convection per sq. ft. of asbestos surface are

$$\frac{29.7 \times 3.415}{0.1885} = 719 \text{ B.t.u. per sq. ft. per hr.}$$

Convection from asbestos surface equals

$$719 - 402.5 = 316.5 \text{ B.t.u. per sq. ft. per hr.}$$

Radiation and convection from the polished silver surface equal

$$\frac{18.16 \times 3.415}{0.1885} = 329 \text{ B.t.u. per sq. ft. per hr.}$$

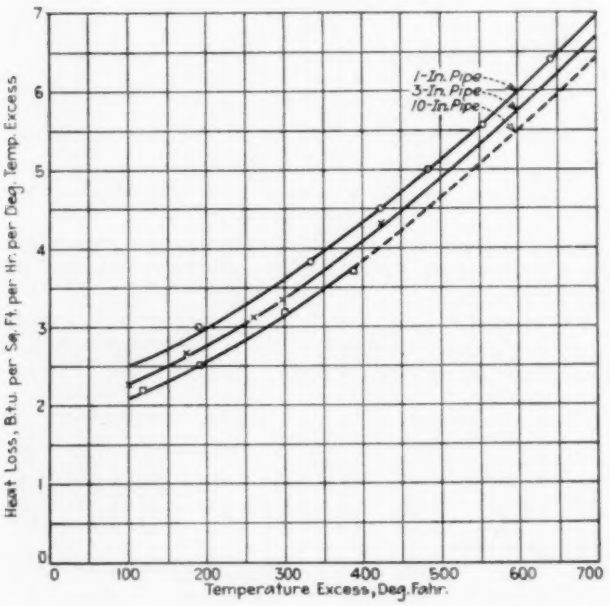

FIG. 4 TOTAL HEAT LOSS FROM BARE PIPES

Radiation from the polished silver surface is

$$329 - 316.5 = 12.5 \text{ B.t.u. per sq. ft. per hr.}$$

Then e for the polished silver surface $= \frac{12.5}{17.23 \times 24.81} = 0.0292.$

HEAT LOSS BY RADIATION AND CONVECTION FROM HORIZONTAL CYLINDERS

The heat loss from nominal 1-in., 3-in., and 10-in. steel pipes has been determined by the author.[3] The experimental curves corrected to a standard room temperature of 80 deg. fahr. are shown in Fig. 4. The total heat loss as obtained from these corrected curves has been separated into its two components, radiation and convection, by the following method.

The emissivity of a rough steel plate having the same characteristic surface as the steel pipes was carefully determined with the radiometer for temperatures of 100 deg. fahr. to 700 deg. fahr.

The heat loss by radiation was then calculated by use of the Stefan-Boltzmann formula

$$R = 17.23 \times 10^{-10} \times e(T_1^4 - T_2^4) \quad \ldots\ldots [2]$$

The radiation loss was then subtracted from the total experimentally determined loss, which gave the loss by convection.

The results of these calculations are given in Table 2.

The heat loss by convection in B.t.u. per hr. per sq. ft. as a function of temperature excess, deg. fahr., pipe to room, is plotted in Fig. 5.

The heat loss by radiation per unit area for the steel surface or

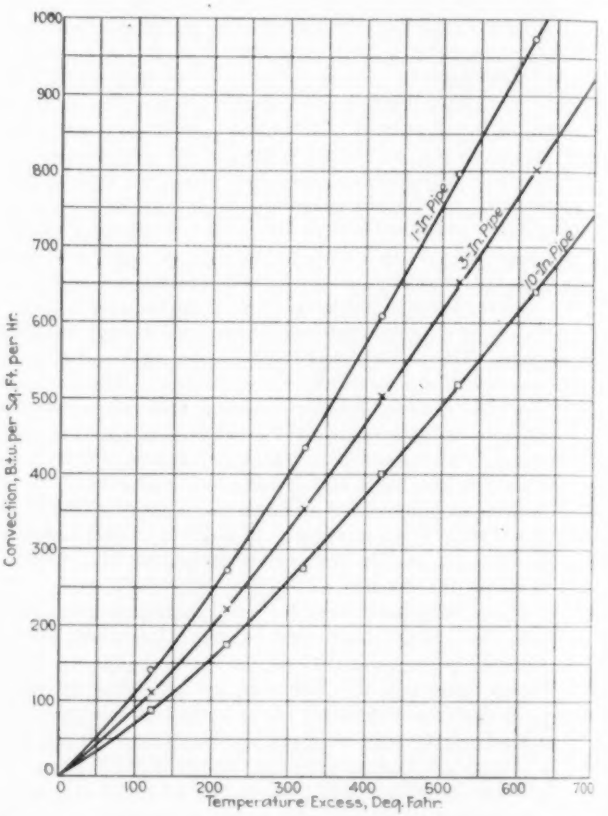

FIG. 5 HEAT LOSS BY CONVECTION FROM THREE SIZES OF PIPE

[3] R. H. Heilman, *Ind. & Eng. Chem.*, vol. 16 (1924), p. 451.

for any surface whose emissivity is known can be readily calculated for the surface in any shape or position or for any temperature excess. However, the calculation of the heat loss by convection for the same conditions is an entirely different matter and presents many difficulties, some of which will have to be solved experimentally. The experimental work can be reduced considerably by the use of dimensional analysis.

One of the objects of this paper is to modify the formulas for horizontal cylinders which have been derived by dimensional reasoning, so as to be able to calculate more accurately the heat loss from horizontal cylinders of any diameter desired.

Free Convection From Horizontal Cylinders

Perhaps the most noteworthy contribution to engineering literature on free convection is the paper by C. W. Rice[4] presented before the A.I.E.E. in June, 1923. In this paper Rice adopts the film theory developed by Langmuir,[5] who states that the reason for the existence of a film around a hot body may be seen as follows: Consider a horizontal wire maintained at a given temperature in a fluid; the fluid adjacent to the wire will become heated and rise, while the cooler fluid of greater density will flow into its place. Thus a convection current is set up by the difference in density between the hot and cold fluids.

At the surface of the wire the fluid is stationary due to viscosity. As we proceed from the surface of the wire the velocity of the convection currents increases until a distance is reached at which the critical-velocity conditions in the fluid are exceeded and the streamline flow bursts into turbulent motion. The discontinuity between the streamline and the turbulent motion constitutes the outer boundary of the film. At the inner boundary the fluid has the temperature of the hot surface and at the outer boundary the temperature of the ambient fluid.

Langmuir's assumption thus reduces the complex problem of free convection to one of conduction in the steady state.

The question of how the film thickness varies with the size and shape of the body and the properties of the ambient fluid is determined by the method of dimensions plus experiments.

The development of the general expression for effective film thickness as given by Rice is as follows: Assume that the film thickness will depend on the temperature difference, the coefficient of density change per degree of temperature change, the acceleration of gravity, and the density and viscosity. Thus the driving force of the convection currents will be proportional to the difference in density produced by the expansion times the acceleration of gravity, and it is the viscosity which opposes this driving force. The motion will obviously depend upon the shape of the hot body. The film thickness may also depend upon the rate at which heat is transmitted through the film, and the specific heat. The addition of these variables also allows us to include the effects of heat carried by slow mass motion within the film. We shall therefore assume that the ratio of film thickness to the size of the body is given by the following expression:

$$B/D = K(\alpha g)^x \ \Delta t^y D^z \mu^p \rho^n k^m c_p^r \quad \ldots\ldots [3]$$

where B = film thickness (L)
D = a linear dimension (L)
K = a numerical constant
α = coefficient of density change per deg. cent. (θ^{-1})
g = acceleration of gravity (LT^{-2})
Δt = temperature difference, deg. cent. (θ)
μ = viscosity of fluid ($L^{-1}MT^{-1}$)
ρ = density of fluid (ML^{-3})
k = heat conductivity of fluid ($HL^{-1}T^{-1}\theta^{-1}$)
c_p = specific heat per gram at constant pressure ($HM^{-1}\theta^{-1}$)

Substituting the dimensions of the various factors in Equation [3] we obtain

$$0 = (LT^{-2}\theta^{-1})^x(\theta)^y(L)^z(L^{-1}MT^{-1})^p(ML^{-3})^n (HL^{-1}T^{-1}\theta^{-1})^m(HM^{-1}\theta^{-1})^r \quad \ldots\ldots [4]$$

from which the following system of simultaneous equations is obtained:

$$\left.\begin{array}{ll} \text{By Length:} & 0 = x + z - p - 3n - m \\ \text{By Mass:} & 0 = p + n - r \\ \text{By Time:} & 0 = -2x - p - m \\ \text{By Heat:} & 0 = m + r \\ \text{By Temperature:} & 0 = -x + y - m - r \end{array}\right\} \quad \ldots\ldots [5]$$

The solution of the simultaneous equations in [5] gives the following relations:

$$\left.\begin{array}{ll} x = n/2 & p = -n - m \\ y = n/2 & r = -m \\ z = 3n/2 & \end{array}\right\} \quad \ldots\ldots [6]$$

From physical considerations we know that the film thickness should increase with the viscosity of the fluid. We therefore change the sign of n and substitute the relations [6] in Equation [3] and obtain

$$\frac{B}{D} = K\left[\frac{v}{(\alpha g\ \Delta t)^{1/3}D^{1/3}}\right]^n\left(\frac{k}{\mu c_p}\right)^m \quad \ldots\ldots [7]$$

where $v = \mu/\rho$ = kinematic viscosity of the fluid.

In order to use this equation we must determine experimentally the values of K, m, and n.

Experimental data on convection in liquids are needed to accurately determine the value of m. For ideal gases this factor does not vary greatly from one gas to another, and for air it may therefore be neglected. However, Rice uses a value of $^1/_4$ for m.

The value for n has been determined by various investigators from tests on heat loss as a function of density of gas. The best average values seem to lie between 0.5 and 0.55. Tests conducted by the author on a silver disk in a very large vacuum oven with pressures of 0.3 to 1 atmosphere indicated a value of approximately 0.53.

The constant K will vary with every system of similar bodies such as cylinders, spheres, flat surfaces, etc., and must be determined experimentally for each system. This constant, according to the results of various investigators, varies between very wide limits.

Derivation of Equation for Convection From Horizontal Cylinders

In accordance with Langmuir's film theory, Rice assumes that the heat lost from a cylinder can be calculated as a problem of conduction in the steady state.

The heat loss will therefore be directly proportional to the conductivity of the film and the temperature drop through it, and inversely proportional to its thickness. For large surfaces such as commercial pipes the film thickness will be small in comparison with the diameter of the pipe, and it is unnecessary to use the logarithmic mean thickness.

The loss by convection is then given by

$$W_c = (A/B)k_{avg.}\ \Delta t \quad \ldots\ldots [8]$$

where
A = area of surface in cm.^{2}
B = effective film thickness in cm.

[4] Chester W. Rice, Trans. A.I.E.E., vol. 43 (1924), p. 131.
[5] Irving Langmuir, Trans. Am. Electrochem. Soc., vol. 23 (1913), p. 318.

k = heat conductivity for the average of surface and ambient temperature in watts cm.$^{-1}$ deg. cent.$^{-1}$
Δt = temperature difference in deg. cent.

The effective film thickness from [7] is

$$B = KD(k/\mu c_p)^m [v/(\alpha g \Delta t)^{1/2} D^{1/2})]^n \text{ cm} \ldots\ldots\ldots [9]$$

where
K = experimental constant depending on the system of similar bodies under consideration
D = diameter of cylinder in cm.
μ = viscosity of fluid at average temperature, cm.$^{-1}$ gram sec.$^{-1}$
c_p = specific heat at constant pressure for average temperature, joule gram^{-1} deg. cent.$^{-1}$
m, n = experimental exponents
$v = \mu/\rho$ = kinematic viscosity of fluid for average temperature, cm.^{2} sec.$^{-1}$
g = acceleration of gravity = 980 cm. sec.$^{-2}$
$\rho = \rho_0 (1 + \alpha t)$ gram cm.$^{-3}$ at temperature t deg. cent.
ρ_0 = density of fluid at 0 deg. cent.
$\alpha = 1/273$ for the case of ideal gases.

Substituting Equation [9] in [8], the general expression for thin films and moderate temperature differences is obtained.

$$W_e = (Ak\Delta t/KD)\ [(\alpha g \Delta t)^{1/2} D^{3/2}/v]^n\ (\mu c_p/k)^m \ldots\ [10]$$

For air at atmospheric pressure Jeans[6] gives

$$\mu = \mu_0 \left(\frac{T}{273}\right)^{0.754}$$

$\mu_0 = 0.0001705$ in c.g.s. units (independent of pressure)
$\rho_0 = 0.00129$ gram per cu. cm. at 0 deg. cent. and 76 cm. Hg
$v = \mu/\rho = 7.05 \times 10^{-6}\ T^{1.754}$ cm.^{2} sec.$^{-1}$
$k = 3.46 \times 10^{-6}\ T^{0.754}$ watts per cm. per deg. cent. at 400 deg. K.

$$\frac{\rho}{\mu} = 7.56 \left(\frac{273}{T}\right)^{1.754}$$

$\mu c_p/k = 0.74$

For large horizontal cylinders in gases and liquids Rice uses the following constants for the three factors K, n, and m in the general equation: $K = 2.12$, $n = 1/2$, and $m = 1/4$. Substituting these values in [10] gives

$$W_e = 0.472A[(\mu c_p/k)(\alpha g/D)]^{1/4}\ (1/v)^{1/2} k\, \Delta t^{5}/_{4} \text{ watts} \ldots [11]$$

Using the constants given above for air and substituting in [11] gives

$$W_e = 0.000785A(1/D)^{1/4} p^{1/2} (1/T_{\text{avg.}})^{0.123}\, \Delta t^{5}/_{4} \text{ watts} \ldots [12]$$

where $A = \pi DL$ = area in sq. cm.
p = absolute air pressure in atmospheres
$T_{\text{avg.}}$ = average of cylinder and ambient absolute temperature, deg. K.

Equation [12] expressed in engineering units is as follows:

$$H_e = 1.015\ (1/D)^{0.25} p^{1/2} (1/T_{\text{avg.}})^{0.123} (\Delta t)^{1.25} \text{ B.t.u. per sq. ft. per hr.} \ldots [13]$$

where D = cylinder diameter in inches
$T_{\text{avg.}}$ = average of cylinder and ambient temperature, deg. fahr. abs.
Δt = temperature difference (deg. fahr.) between surface and air.

If we calculate the heat loss from a 3.5-in. horizontal pipe at a temperature of 580 deg. fahr. with room temperature at 80 deg. fahr. from Rice's modified equation, we have

$$H_e = 1.015 \times (1/3.5)^{0.25} \times 1^{1/2} \times (1/750)^{0.123} \times (420)^{1.25} = 626 \text{ B.t.u. per sq. ft. per hr.}$$

Similarly for the 1.315-in. and the 10.75-in. diameter pipes, we have 799 and 473 B.t.u., respectively.

The experimentally determined values for the three pipes as taken from Fig. 5 are 608, 500, and 398 B.t.u., respectively. This indicates that the values as calculated from Rice's modified equation are 24, 20, and 16 per cent higher than the experimental values.

Similar calculations for lower temperatures indicate slightly lower percentages, and for higher temperatures, slightly higher percentages.

Changing the value of K in Rice's equation would bring the calculated and experimental values in line for only one pipe size and at only one pipe temperature. It is readily apparent that the exponent for the factor $1/D$ is the one which is the most out of line.

By calculation it is found that the exponent for the shape factor which best fits the experimental results for the horizontal pipes is 0.2 instead of 0.25. However, if we wish to change the exponent for the shape factor to 0.2 and yet maintain the general form of Equation [10], it will be necessary to change the value of n from 0.5 to 0.533.

Changing n to 0.533 in [10] results in a change of the exponents of Δt from 1.25 to 1.266, v from 0.5 to 0.533, and g from 0.25 to 0.266. Letting $C = K$ times the numerical constant obtained in [12], the resulting final equation is

$$W_e = CA \left(\frac{1}{D}\right)^{0.2} p^{0.533} \left(\frac{1}{T_{\text{avg.}}}\right)^{0.181} \Delta t^{1.266} \ldots\ldots [14]$$

The average value for C as obtained from the experiments on the horizontal pipes in engineering units is 1.016, or

$$H_e = 1.016 \left(\frac{1}{D}\right)^{0.2} p^{0.533} \left(\frac{1}{T_{\text{avg.}}}\right)^{0.181} \Delta t^{1.266} \text{ B.t.u. per sq. ft. per hour} \ldots\ldots [15]$$

It is generally accepted that the value for Δt is very close to 1.25. However, it has been found during the course of this investigation that the exponent is not always constant but generally varies slightly with the temperature excess. For example, if we take the convection curve for the 3-in. pipe shown in Fig. 5 and analyze it carefully by means of the equation $y = ax^b$ or $\log y = \log a + b \log x$, taking off values from the experimental curve and solving the resulting simultaneous equations we find that the average value of b from 100 to 350 deg. temperature excess is 1.19 and from 350 to 700 deg. is 1.23, with an average for the entire curve of approximately 1.21.

Similar analysis from the curve obtained by Langmuir on a silver disk (part of which is shown in Fig. 6) gives from 100 to 700 deg. a value of 1.23, and from 700 to 1100 deg. a value of 1.19.

Also analysis of a curve obtained by the author on a silver disk 6.55 in. diameter and 0.8 in. thick gives values of b from 100 to 350 deg. of 1.23, and from 350 to 700 deg. of 1.31.

Analyses of other curves obtained by various investigators show the same characteristics. It is therefore readily apparent that while the variation with temperature excess can be forced to follow an exponential straight line having a given slope, with little error, in order to determine accurately the true heat loss it is necessary to introduce another factor into the equation which will take care of this variation. The factor $(1/T_{\text{avg.}})$ serves to fill in this gap.

[6] J. H. Jeans, The Dynamical Theory of Gases, Cambridge Univ. Press, 2nd edition, 1916, p. 317.

If we take Equation [15] and apply it to the experimental curves given in Fig. 5, we find that it fits almost exactly over the entire range of the curves.

Convection Losses From Various Geometrical Shapes

Vertical Cylinders. Apparently no experiments have been conducted on vertical cylinders to determine accurately the effect of diameter on the heat loss. Griffith and Davis[7] conducted experiments on a 6-in.-diameter pipe to determine the effect of height on the convection loss. They obtained a minimum loss for a height of approximately 3 ft. and a maximum loss for the shortest height tested, which was 1.8 in.

The longest cylinder tested was 8 ft. 8 in. in height, and the exponent for the variation of convection with temperature for this particular height was 1.34.

Rice,[4] using the value of 1.333, calculates the value of n in the general equation and obtains a value of 0.666. Using this value, the shape factor in Equation [10] cancels out entirely, which indicates that for long vertical cylinders the loss per unit area is independent of size.

It is very probable that this assumption is not correct, as Griffith and Davis obtained various values for the exponent of Δt ranging from 1.34 to 1.17 for the various heights tested, with an average value of 1.24 for the eight different lengths. Using any one of the exponents with the exception of 1.333 in Equation [10] will cause the shape factor to appear in the equation. Also, as was noted for the case of the horizontal cylinders, changing the exponent of Δt from 1.25 to 1.266 caused a change in the exponent for the shape factor from 0.25 to 0.20. Thus a slight change in the exponent of Δt causes a very important change in the exponent of $(1/D)$ or $(1/H)$.

To obtain some experimental data on the effect of size on the loss from vertical cylinders, a 1-in. and a 3-in. pipe each 3 ft. long were placed in a vertical position and tested. These tests resulted in two separate total-heat-loss curves being obtained, which were parallel to each other and also parallel to the curves for the horizontal pipes but somewhat above them. These tests prove conclusively that for heights of 3 ft. the diameter of the pipe has a decided effect on the heat loss per unit area. Since Griffith and Davis obtained practically the same heat loss per unit area for the 3-ft. and 8-ft. heights, it is reasonable to expect that for heights above 3 ft. the shape factor would enter into the equation as for the 3-ft. tests. Therefore, for vertical cylinders 3 ft. in height or over, it is suggested that Equation [14] be used in calculation of the convection losses. The results of the experiments conducted on the two vertical pipes indicated the same exponent for $(1/D)$ and also a value of 1.235 for C. Therefore, for long vertical cylinders in air at atmospheric pressure, Equation [14] becomes

$$H_c = 1.235 \left(\frac{1}{D}\right)^{0.2} \left(\frac{1}{T_{\text{avg.}}}\right)^{0.181} \Delta t^{1.266} \quad \ldots\ldots [16]$$

Plane Surfaces. To determine the effect of height on plane vertical surfaces, experiments were conducted on three electrically heated brass disks heavily silverplated and highly polished, in order to reduce the radiation effect as much as possible. The dimensions of the disks were as follows: 3.47 in. diam., 0.758 in. thick; 6.55 in. diam., 0.80 in. thick; and 9.97 in. diam., 0.90 in. thick.

The test results showing the convection loss in B.t.u. per sq. ft. of surface is given in Fig. 6. Taking the vertical height as equal to the square root of the area of one of the sides, calculations show that here again the exponent for the shape factor is 0.20. The experimental results for the three disks indicate a value of 1.394 for C. If we substitute this value for C in Equation [14] and calculate the convection loss for various temperature excesses we find that the equation fits the experimental curves with very little error for the entire temperature range.

The effect of shape factor for vertical walls is a very important item in engineering industry. For this reason further investigational work should be carried out on larger plane surfaces than were used during this investigation. While the experiments conducted prove conclusively that the effect of size is very evident for diameters up to 10 in., they do not indicate how far the exponent can be used for larger diameters or vertical heights.

Griffith and Davis[7] state that for heights above 8 or 12 in., the heat loss per unit area is, roughly, independent of size. However, they obtain a greater heat loss per unit area for a vertical plate approximately 50 in. square than was obtained during this investigation for a vertical disk 10 in. in diameter or than Langmuir[5] obtained for a vertical disk 7.5 in. in diameter. It is very probable that Griffith and Davis did not have the correct emissivity coefficient when calculating the radiation correction. In the case of the 10-in. disk and Langmuir's 7.5-in. disk, the radiation correction was always lower than 3.5 per cent for the entire temperature range of the experiments.

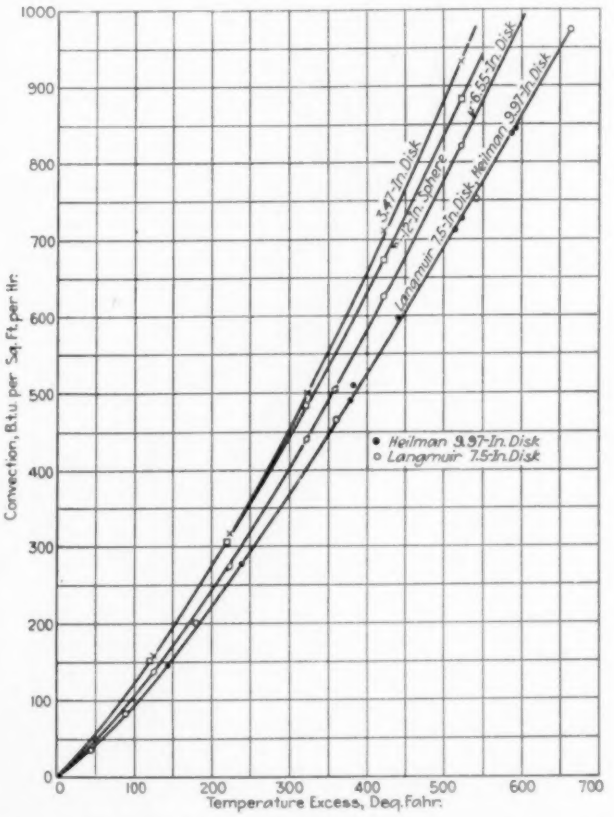

Fig. 6 Heat Loss by Convection From Spheres and Disks

To obtain further data on the effect of height on convection losses a test was conducted on a strip of Nichrome IV ribbon 0.50 in. wide, 0.05 in. thick, and varying in length from 2 in. to 9 ft. This ribbon was suspended in a vertical position and heated by passing a current of electricity through it. To take care of lead-wire losses, small voltage taps were silver-soldered to the ribbon at a distance of 6 in. from each end in one case, and at a distance of 2 in. from each end in the other tests.

[7] Special Report 9, Department of Scientific and Industrial Research, London, England.

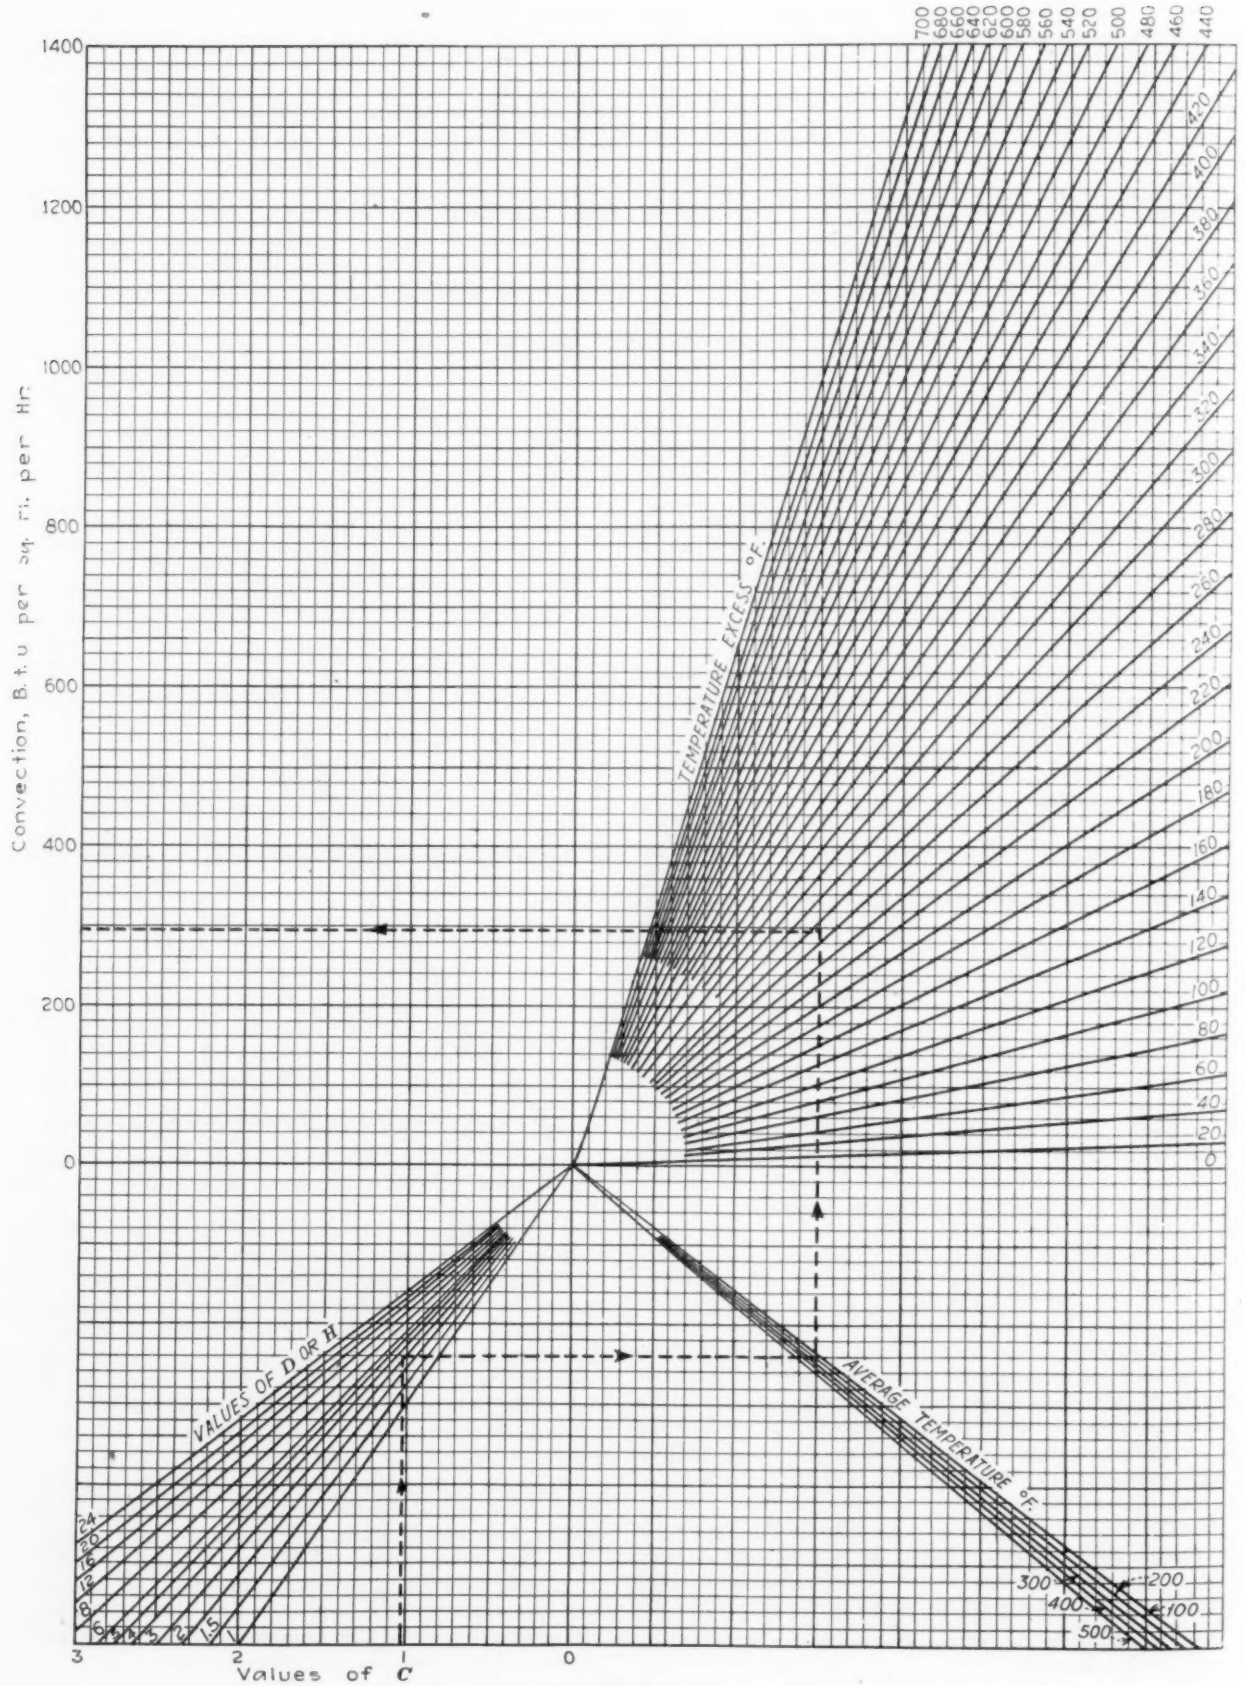

FIG. 7 HEAT TRANSMITTED BY CONVECTION

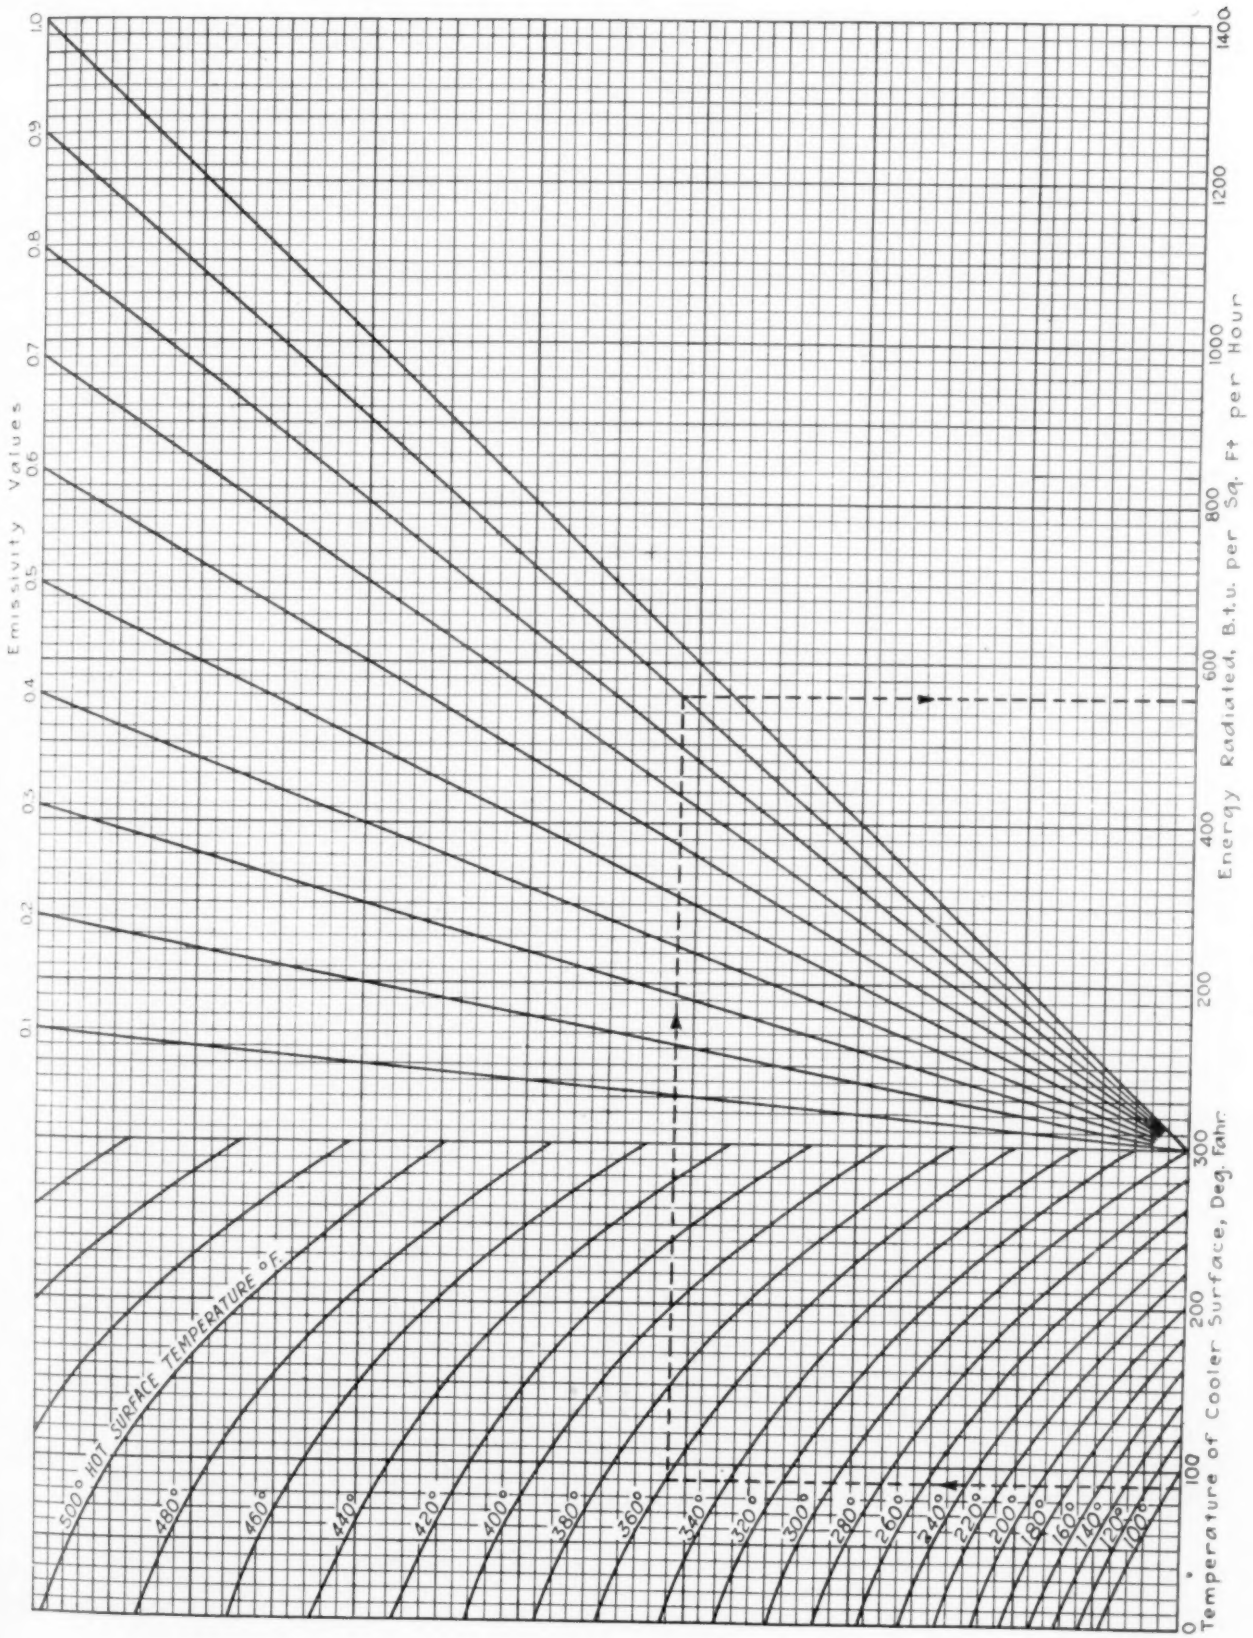

FIG. 8 HEAT TRANSMITTED BY RADIATION

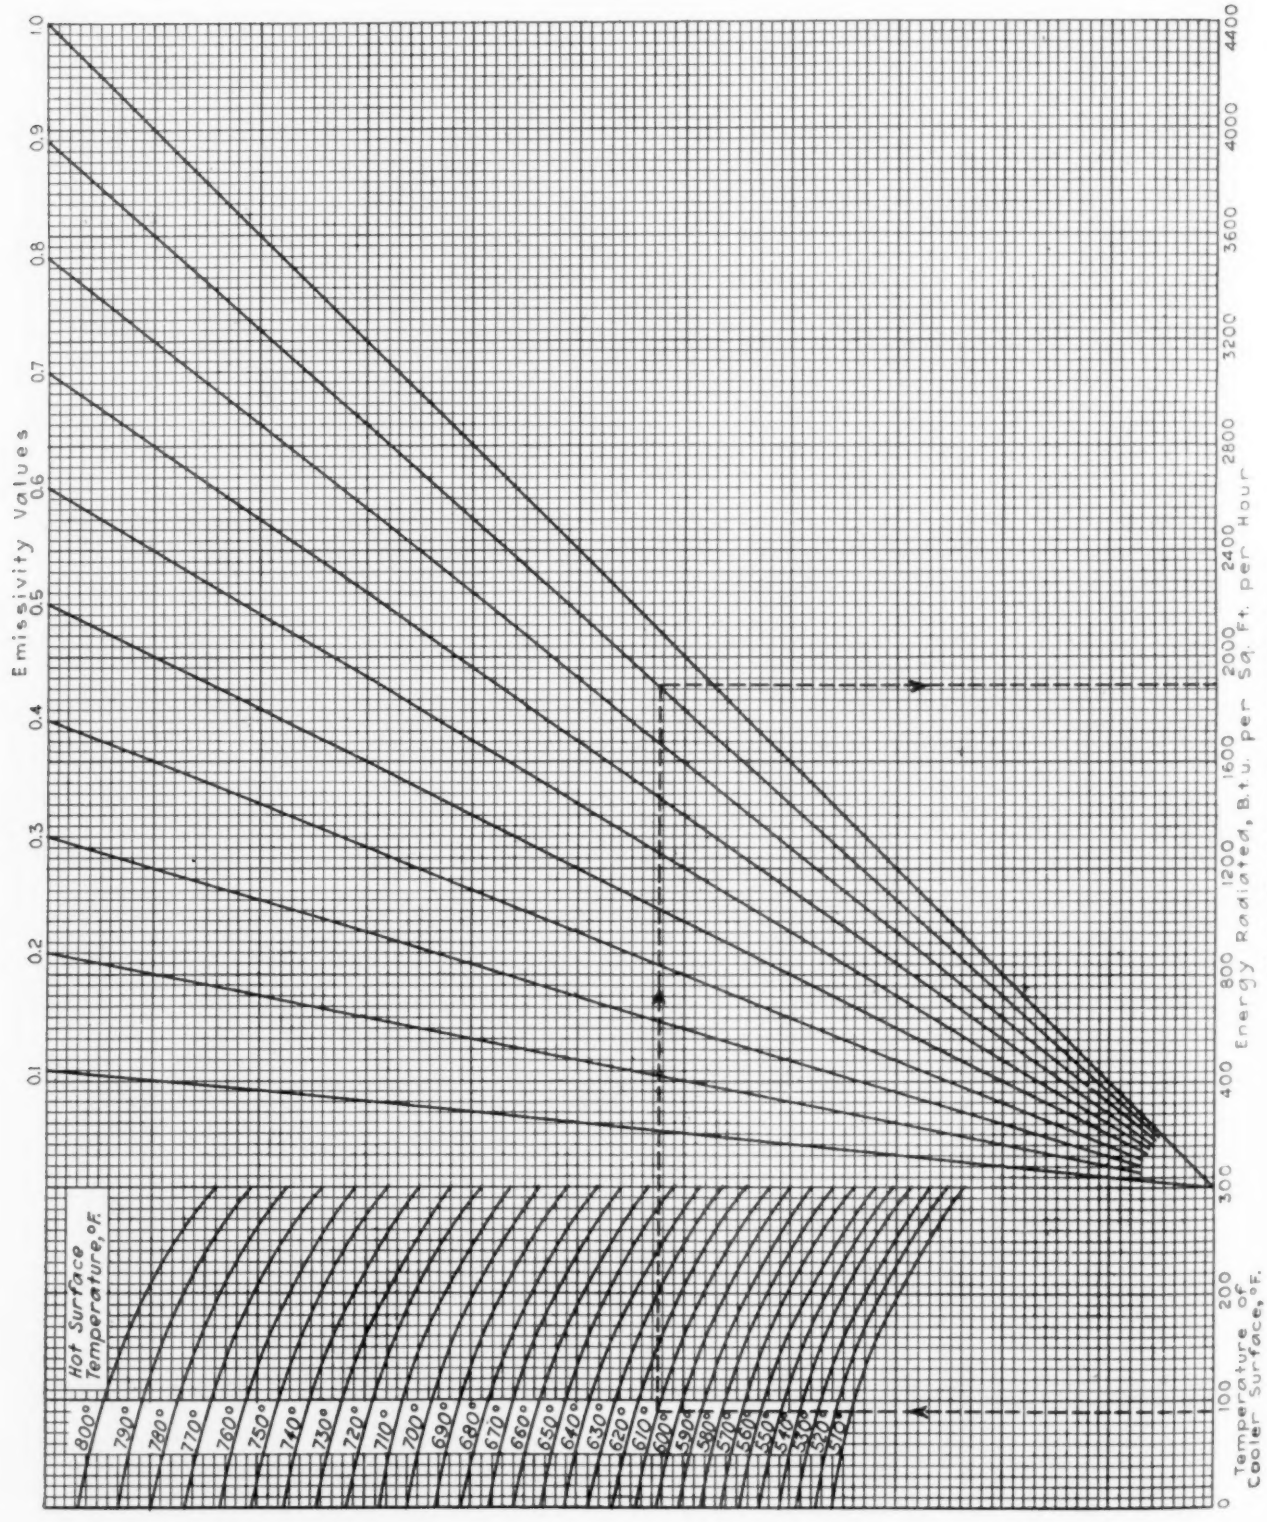

FIG. 9 HEAT TRANSMITTED BY RADIATION

For temperature excesses up to 350 deg. fahr., the heat loss per unit area was roughly independent of length for lengths above 2 ft.

While these tests throw some additional light on the vertical height at which the heat loss becomes constant for a vertical wall, they do not indicate conclusively the exact height, as the modification of the convection currents about a thin vertical ribbon of very small width in comparison to height is probably somewhat different from what it is for a vertical wall having a width comparable to its height.

Additional tests on larger plane surfaces are needed to definitely settle this question.

However, until further experimental data have been obtained, it is suggested that Equation [14] with a value of 1.394 for C be used for vertical surfaces, assuming the heat loss to become constant for heights greater than 24 in., or $(1/24)^{0.2} = 0.549$.

The heat loss from a plane surface in a horizontal position facing upward is greater than for the same surface in a vertical position, also the heat loss in a horizontal position facing downward is less than for the same surface in a vertical position. Langmuir found the convection upward from a 7.5-in. disk to be about 12 per cent greater than for the disk in a vertical position. He also found the convection downward to be about one-half as much as the convection upward.

Griffith and Davis found the convection upward from a 50-in-square plate to be about 28 per cent greater than for the vertical position, and the convection downward to be about 34 per cent less than the convection in the vertical position.

Here again the size of the plate would have a marked effect on the modification of the convection currents and the consequent convection losses in the various positions.

More experimental work is needed on various-size plates in the three positions to determine accurately the effect of size and position.

If we take the percentages obtained by Griffith and Davis for the present, we shall have for the value of C in our equation, 1.79 for the horizontal position facing upward and 0.89 for the horizontal position facing downward.

Spheres. One test was run on a 12-in-diameter cast-iron sphere during this investigation. The convection loss from this sphere is shown in Fig. 6. The shape of the curve is slightly different from that of the vertical disks, but the curve can be very closely approximated by Equation [10], using 1.82 for the value of C. The sphere shows a very great rate of heat loss in comparison with the other shapes tested, the factor C being slightly higher than obtained for the horizontal plate facing upward.

Total Heat Loss From Various Shapes and Surfaces

It is seen from the discussion preceding that the heat loss by free convection from the surfaces of the principal geometrical shapes met with in engineering practice can be approximated with great accuracy in most cases by the equation

$$H_c = C \times \left(\frac{1}{D}\right)^{0.2} \times \left(\frac{1}{T_{avg.}}\right)^{0.181} \times \Delta t^{1.266} \text{ B.t.u. per sq. ft. per hr.}$$

The heat loss by radiation can be calculated by means of the equation

$$H_r = 17.23 \times 10^{-10} \times e(T_1^4 - T_2^4) \text{ B.t.u. per sq. ft. per hr.}$$

Table 1 in the first part of the paper gives values of e for some of the surfaces met with in practice. It was the author's intention to include a great many more surface values in this paper. However, it is his opinion that practically all the surfaces encountered in engineering practice (other than lustrous or bright metallic surfaces) have practically the same emissivity value as was found for asbestos paper or the rough steel plate. Some of the surfaces included in this list are brick, stone, wood, plaster, paper, cloth, various colored paints, etc.

It should be mentioned here that these values are intended only for what might be termed "black" heat radiation, as no attempt has been made to determine emissivity values for solar radiation during this investigation.

The results of the emissivity determinations show a somewhat greater heat loss by radiation than was formerly believed to exist for the various surfaces commonly met with in practice. For instance, a commercial rough steel pipe in a room at 70 deg. fahr. with the pipe surface at 100 deg. fahr., loses over 60 per cent of the total heat loss from the surface by radiation. The same pipe at a temperature of 1000 deg. fahr. loses about 86 per cent of its heat by radiation.

To enable the engineer to readily determine the total heat loss from various surfaces the author has included several charts which eliminate all calculations for surface temperatures up to 700 deg. fahr. These charts have been carefully drawn and should give an accuracy of 1 per cent or less in most cases, except for the very low temperature excesses.

The dotted lines show the method of procedure for a 3-in. O.D. horizontal cylinder at a temperature of 360 deg. fahr. with a room temperature of 90 deg. fahr. or a temperature excess of 270 deg. and average temperature of 225 deg. Emissivity value, 0.9.

Referring to Fig. 7, the dotted line shows 298 B.t.u. loss by convection and Fig. 8 shows 560 B.t.u. loss by radiation, or a total loss of 858 B.t.u. by radiation and convection.

The following table gives the values of C to use in Fig. 7 for the various shapes.

Horizontal cylinders	1.016
Long vertical cylinders	1.235
Vertical plates	1.394
Horizontal plates facing upward	1.79
Horizontal plates facing downward	0.89
Spheres	1.82

As mentioned previously, the actual convection loss per unit area from small horizontal plates and short vertical cylinders decreases as the size of the plate and the height of the cylinder increase. The exact size or height at which the loss becomes constant is not known. Until further experimental work is done it is suggested that 24 in. be taken as the limit.

In the case of short vertical cylinders, assuming that the effect of height varies as the 0.2 power for lengths up to 24 in. and is independent of height for lengths above 24 in., the approximate convection loss can be obtained from Fig. 7 as follows:

Take, for example, the heat loss by convection from a 2-in-diameter cylinder 12 in. in height, at a temperature of 360 deg. fahr. with room temperature of 90 deg. fahr. According to Equation [14], the loss from a horizontal cylinder varies directly as the shape factor or $(1/D)^{0.2}$, therefore, for a short vertical cylinder the loss should vary directly as the shape factor and also directly as the height factor or $(1/D)^{0.2} \times (1/H)^{0.2}$, or for the 2-in-diameter cylinder 12 in. in height, we have $2 \times 12 = 24$. Using the value of 24 for D or H in Fig. 7 and a value of 2.33 for C, which is the value to use for short vertical cylinders, we proceed from 2.33 for C vertically to 24 for D or H, thence horizontally to 225 deg. fahr. average temperature, thence vertically to 270 deg. fahr. temperature excess, and thence horizontally to 450 B.t.u. loss by convection from the short vertical cylinder. When the product of $D \times H$ for short vertical cylinders is greater than 24, it will be necessary to assume the probable position of this product above the values of D or H

Fig. 9 Heat Transmitted by Radiation

shown in Fig. 7, as the values are given in the diagram up to only 24 in. so as not to conflict with the statement given above that the loss per unit area probably becomes constant for values of D or H above 24 in.

ACKNOWLEDGMENT

In conclusion, the author wishes to express his thanks to Mr. R. W. Ortmiller, who has assisted in securing the data for this paper.

Discussion

W. J. KING.[8] This paper constitutes a valuable contribution to the literature of heat transmission. In addition to adding to our knowledge of the subject, it calls attention to the thin spots where more information is badly needed.

The determinations of the radiation emissivities of various surfaces were particularly interesting. The methods and care used in these measurements inspire confidence in their accuracy. The results are confirmed by some similar tests which have been made recently at Schenectady, except that we found considerably lower values for our particular kind of steel surface. It is very difficult to specify exact values for the emissivity of metallic surfaces because it varies so much with the state of oxidation. We found values as low as 0.68 for a steel plate as received, and 0.34 for the same plate brightened up with fine sandpaper. Likewise, the emissivity of aluminum paint may vary with the amount and kind of vehicle from 0.28 for spar varnish to 0.55 for amyl acetate. We also confirm the statement that most nonmetallic surfaces encountered in engineering practice have an emissivity of about 0.95, at temperatures below incandescence. Apparently the two values of 0.80 for black and white lacquer at 100 deg. are misprints.

Are the conductivities for lampblack in Fig. 3 per inch or per foot of thickness?

It is unfortunate that the determinations of the convection components of the heat loss from horizontal pipes were made with steel pipes having a high emissivity, instead of with polished silver surfaces. At the higher temperatures the radiation component is several times the convection. If the emissivity of the original pipe happened to be 0.90 instead of 0.95, as determined for an ostensibly similar steel plate several years later, the convection in the case of the 10-in. pipe at 700 deg. would have been apparently 156 B.t.u. more, representing an error of 24.4 per cent. This same uncertainty detracts from the value of Griffith and Davis' work on the convection from lamp-blacked cylinders.

In re-deriving Mr. Rice's formula for convection from horizontal cylinders, the author seems to have fixed his attention upon Rice's *approximate* equation using the value of $n = 0.5$ in Equation [7] as convenient for rough calculations, and appears to have completely overlooked the fact that Rice gave $n = 0.54$ and $K = 2.60$ as the *exact* values. Using these latter values in Equations [7] and [10] gives exactly the same results as Equation [15]. Although the author might have spared himself this repetition, he has nevertheless independently confirmed Rice's work, so that the formula for free convection for long horizontal cylinders seems to be rather well established.

In the section on convection from vertical cylinders, the author mentions Rice's conclusion that for long, vertical cylinders the loss per unit area is independent of size, but says that, "It is very probable that this assumption is not correct, as Griffith and Davis obtain values of the exponent of Δt ranging from 1.34 to 1.17 for the various heights tested, with an average value of 1.24 for the eight different lengths." It should be observed that Rice specifies *long*, vertical cylinders, whereas the last four of Griffith and Davis ranged from 1.83 in. to 11.3 in. in height, or 0.266 to 1.65 diameters.

Apparently both Rice's and the author's formulas for vertical cylinders are not quite correct, and in some cases may result in very considerable errors. Rice's formula does not contain the diameter as a factor in the case of long cylinders, and the author's method is dimensionally unsound in the case of short cylinders. It is suggested that since the loss from a horizontal cylinder varies as the shape factor or $(1/D)^{0.2}$ (dimensionally $L^{-0.2}$), for a short, vertical cylinder, the loss should vary directly as the shape factor and also directly as the height factor or $(1/D)^{0.2} \times (1/H)^{0.2}$ (dimensionally $L^{-0.2} \times L^{-0.2} = L^{-0.4}$). Since all the other exponents remain the same, this latter method cannot be used without destroying the dimensional equality. For long cylinders, since the coefficient in Equation [16] is greater than that in [15], it would appear that the convection would be greater in the vertical than in the horizontal position, at atmospheric pressure, which does not seem reasonable and is contradicted by Rice's results.

Although experimental data to confirm it are lacking, it seems probable that for short horizontal or vertical cylinders both the length and diameter enter into the equation in such a way that the sum of their exponents is equal to something close to —0.2. When horizontal the effect of diameter predominates, and when vertical the effect of height predominates. For the horizontal position, as a rough guess, the length may enter the equation as $(1/L)^{0.05}$ and the diameter as $(1/D)^{0.15}$; and conversely for the vertical position. Upon plotting the graphs of these two functions the shapes of the curves suggest that they would account for the known experimental facts for both long and short cylinders, as they become nearly constant for large dimensions and change rapidly for small values.

Likewise, for vertical planes it is probable that both height and width enter into the formula, with the effect of height predominating. In the horizontal position the exponents of the two dimensions must be the same. This would account for the discrepancy between the ratios for convection in the vertical and horizontal positions as found by Langmuir and by Griffith and Davis.

It is to be hoped that the author will continue his experiments with vertical pipes and with plane surfaces. If he does so with the same thoroughness which characterizes his measurements of radiation emissivities, the aforementioned difficulties will no doubt be straightened out in due course.

CHARLES H. HERTER.[9] The author's contribution on surface heat transmission is most interesting and valuable. He deserves much credit for endeavoring to determine separately the effects of radiation and convection. This important work should be continued. After perusing the first paragraph one expects to find emissivity coefficients applicable to heat insulation and refrigeration in which fields the temperature differences diminish to 50 and as low as 5 deg. fahr.

In Figs. 5, 6, and 7 the convection curves terminate at 0 for 0 deg. difference, but in Fig. 4 the curves for total heat loss apply only to temperature differences from 100 to 700 deg. Engineers must therefore continue to make their own assumptions as to the heat-absorbing capacity of dry refrigerating surfaces at the low differences usually met with. It is conceded that at 30 deg. temperature difference between pipe and cold air the value of K per degree difference is greater than at 10 deg. difference because the convection is weak at small differences; but the exact rate of change in the curve is not well established. In refrigerating practice the problem is further complicated by the presence of condensed moisture and snow of varying degrees of density on

[8] Engineer, General Electric Co., Schenectady, N. Y.

[9] New York, N. Y.

the cooling coils, also by the direction of air flow along or across these pipes, by their grouping, and finally by their surface temperature, which may not be as constant or uniform as one would wish for best effect.

If therefore these heat and temperature measurements could actually be extended into the field of lower temperatures, to produce these missing data, all engineers concerned with air conditioning and the preservation of perishable products would greatly appreciate any efforts along these lines.

In 80 per cent of these applications horizontal cylindrical pipes down to $^1/_2$ in. outside diameter are used; the remainder may be flat surfaces, mostly vertical, but in no cases in practice are spheres used for heat transmission, even though a sphere is a geometrical shape of particular fascination to a physicist.

F. G. HECHLER.[10] It seems unnecessary to say that this paper is a welcome contribution to the literature on surface transmission of heat and that it should help materially in correcting some popular misconceptions. One of these deals with the heat transmission through air spaces as commonly used in walls of dwellings. Although the paper does not refer to air spaces, the data should with slight modification be applicable.

It has long been the practice in this country to calculate the heat transmission through such an air space by assuming that the resistance of the space is equivalent to that of two additional surfaces under still-air conditions. The value of the surface coefficient for still-air conditions is assumed to be 1.34, which is the mean value obtained from a few tests. This gives for the thermal resistance of an air space $2 \div 1.34 = 1.49$, a value which is quite generally used for calculating the heat losses through walls, though it does not appear to be based either on tests or a rational analysis of the problem. During the past few years data from various sources have become available which show that the value 1.49 is entirely too high and that if for simplicity and convenience a single value is desirable, the value 1.00 would be much better. In a well-insulated wall where the total thermal resistance is high the effect of the air space is masked and it makes little difference whether we use 1.00 or 1.49; but for uninsulated walls with low thermal resistances the error may be large; for example, in a wall plastered inside and stuccoed outside, both on metal lath, the heat transmission calculated with the factor 1.49 will be about 20 per cent too low.

In vertical air spaces convection and conduction are closely connected, their relative values depending largely on the width of the space. For very narrow spaces convection is greatly restricted, but conduction increases so rapidly that the total heat transfer gets larger. However, for spaces wider than about 0.5 in. there appears to be but little change with width. In practice air spaces are seldom less than 0.75 in. nor more than 4 in. wide, and it is interesting to calculate the heat transfer across such a space with the data now available.

Some years ago the Bureau of Standards published such a table in which the radiation values were based on an emissivity coefficient of 70 per cent of that for a black body. Shortly afterwards the results obtained by Griffith and Davis in England indicated that this coefficient should have been much higher. This is confirmed by Mr. Heilman, who finds that for most building materials the coefficient should be 93 per cent. This of course magnifies the effect of radiation.

The average temperature in building walls as well as the temperature range in the air space is somewhat below the useful range of the curves given in the paper, so that it is necessary to calculate the desired data from the equations for convection and radiation. It is also of interest to compare the equations given by Heilman with those proposed by Griffith and Davis. If we choose a mean temperature of 40 deg. fahr. (500 deg. abs.) in order to reduce Heilman's Equation [14] for convection to its simplest form we have the following comparison:

	Hc, convection	Hr, radiation
Heilman	$0.248\ \Delta T^{1.266}$	$16.024 \times 10^{-10}(T_1^4 - T_2^4)$
Griffith and Davis	$0.30\ \Delta T^{1.25}$	$16 \times 10^{-10}(T_1^4 - T_2^4)$

where ΔT represents the temperature excess and T_1 and T_2 are the absolute temperatures in degrees fahrenheit. The two equations for radiation loss are almost identical, but those for convection differ considerably, though it should be noted that the difference decreases with increasing values of ΔT. The coefficient as given by Heilman depends on the average absolute temperature, but for the small temperature range found in walls this has little effect on the coefficient which is 0.252 at 0 deg fahr. and 0.246 at 70 deg. fahr.

The interesting fact, however, is the rapid increase of the convection loss with increasing temperature differentials. For example, with a mean temperature of 40 deg. fahr. the value of Hc for $\Delta T = 1$ deg. is 0.248 B.t.u., while for $\Delta T = 10$ deg. and the same average temperature $Hc = 4.58$ B.t.u., which is equivalent to 0.458 B.t.u. per deg.; this is nearly twice as great as for $\Delta T = 1$. Changing the temperature differential, however, has no effect on the radiation loss if the mean temperature remains constant.

The radiation loss is independent of the distance between the surfaces and applies therefore to air spaces in walls. The convection and conduction losses, however, depend on the width of the space; the foregoing equations for Hc apply only for free-air convection and not to the condition found in air spaces where convection currents are greatly restricted. Fortunately Griffith and Davis did some experimental work to determine the convection and conduction losses in air spaces of different widths, and from their data it appears that the sum of conduction and convection in air spaces is about 60 per cent of the value for free convection. Applying this factor to Heilman's equations the results given in Table 3 have been calculated for average temperatures varying from 20 deg. to 70 deg. and for values of ΔT of 1 and 10 deg.

TABLE 3

Average temperature deg. fahr.	T_1	T_2	Hc free air, total	Hc^1 air space, per degree	Hr per degree	Ht total, per degree	Air space resistance, $= \frac{1}{Ht}$
20	480.5	479.5	0.250	0.16	0.71	0.87	1.15

60	525.0	515.0	4.557	0.27	0.90	1.17	0.86
70	530.5	529.5	0.246	0.15	0.96	1.11	0.90
70	535.0	525.0	4.539	0.27	0.96	1.23	0.81

Hc = convection loss in free air, Equation [14].
Hc^1 = convection and conduction loss in air space = $0.6Hc$.
Hr = radiation loss.
$Ht = Hc^1 + Hr$.

The surprising feature to many who have not given the matter much attention is the important part that radiation plays in the heat transfer across air spaces at these low temperatures. Radiation accounts for about 80 per cent of the total and convection and conduction for only 20 per cent when the value of ΔT is 10 deg. However, if ΔT increases, without changing the value of the average temperature, the latter losses increase rapidly, as may be seen by comparing the values for temperature differences of 1 deg. and 10 deg.

The last column gives the resistance of the air space. These values should be compared with the conventional value of 1.49.

[10] Professor of Engineering Research, Pennsylvania State College, State College, Pa. Assoc-Mem. A.S.M.E.

It is significant that only at the lowest temperatures and for 1 deg. temperature difference is the resistance greater than 1.00. For this part of the country the average temperature of an air space is probably about 40 deg., and the value of ΔT will be in the neighborhood of 10 deg., though this may vary considerably with the kind of wall, so that for ordinary calculations the thermal resistance of an air space may be taken as 1.00. If the actual temperatures are known or if they can be accurately predicted, the appropriate value for the resistance may be calculated.

P. Nicholls.[11] The author and the company which is supplying the funds are to be congratulated that a serious attempt is being made to put the general case of the transfer of heat from surfaces in contact with air on a more assured basis, and it is to be hoped that the work will be continued by the author and his results confirmed by others.

The correctness of the deductions for the loss by convection depends entirely on the accuracy of the measurement of the radiation. In view of this it would have been better if the experimental work on the measurement of the radiation had been published in greater detail either in this or a previous paper. It can be presumed that every care was taken, but one is justified in asking for a fuller treatment with a discussion of the possible sources of error and, as far as possible, attempts to evaluate their magnitude. Confidence in the radiation values is necessary for the acceptance of the deductions on the convection law.

The following are some points in the radiation measurement not dealt with:

(1) What was the exact design of the radiator; presumedly it lost heat from all its surfaces? What assurance was there that the loss of heat from the part of its surface exposed to the receiver was the same as that from the rest of the surface?

(2) Apparently the assumption was made that the radiation loss of the radiator to other objects than the disk of the receiver was the same as that to the disk; how far was this shown to be true?

(3) Are the radiometer deflections dependent on the temperature of the cold side of the junctions, or what assurance was there that the temperature of the cold junctions remained constant during an observation?

(4) It would seem necessary that the rate of loss of heat from the disk should be proportional to the rate it receives heat; would it not be preferable to water-cool the enclosing case of the receiver so that its temperature could be the same for all tests? Also to use a water-cooled enclosure to surround the radiator, and to make its interior surface of the same finish as that of the exterior of the radiometer? Would it not be still better to give all surfaces a platinum black finish so that the radiator would have full exposure to that finish?

(5) Assurance is desirable that the radiation constant of the steel surface used in the radiation tests corresponded exactly with that of the steel pipes used in the total heat-loss tests, because the derivation of their convection loss depends on the values being the same.

Some of these questions would not have much influence on the results obtained, but information on them is desirable; the suggestions are not made critically as it is recognized that the work is still in its early stages. The incompleteness of the details of test procedure and of the data obtained as given in the report of the similar work done by the English Department of Scientific and Industrial Research militated against its availability and usefulness.

The author's main experimental results are on horizontal cylinders; since he will have much data on loss from canvas coverings, would it not be well to treat those surfaces as he has done the bare pipes?

One would not imagine that the diameter would have as much influence on heat transfer from vertical as from horizontal cylinders, although apparently it is suggested that the same index for D be used; however, to remove doubt, the summation of results in the table giving values for C could well be expanded to include the value to be used for D for each shape. It is also suggested that the experimental data do not warrant the number of significant figures used for any of the values of C except for the horizontal cylinders.

The form of the diagrams used for the computations is most convenient, and their use will probably give results more nearly corresponding to actual heat transfer than are usually arrived at by other methods of computation.

A general treatment of heat transfer by radiation for the use of engineers is needed, particularly to explain the effect of the situation and the size of the surface relative to its surroundings. The most complete treatment in English is given in Bulletin No. 1 of the Department of Heating and Ventilating of the University of London, "The effect of the shape and surroundings of a hot surface on the radiation from it," by A. H. Barker and M. Kinoshita. The theoretical treatment is complete although the supporting experimental data are not conclusive.

Author's Closure

In reply to Mr. Nicholls' discussion, the author agrees with him that a fuller discussion of the design and the experimental work with the radiometer would have been desirable. However, it was felt that the results of the experiments would be of the most value to the engineering profession, and to include both in the same paper would have made the paper too long.

If time will permit a complete paper on the radiometer and experimental determinations will be prepared in the near future. For the present, however, the author will try to answer a few of Mr. Nicholls' questions.

(1) The radiator was constructed of $^1/_4$ in. thick brass, so as to assure a uniform temperature throughout its surface. It consisted of a circular disk approximately 3.5 in. in diameter and 0.75 in. thick, with a cavity approximately 3.25 in. in diameter by 0.25 in. thick. This cavity was completely filled with an alundum plate containing a uniformly wound heating element. The lead wires were brought out through small holes and also the three supporting wires so that there were no obstructions or protruding screws.

The whole outer surface of the receiver was heavily silver-plated and highly polished so that the radiation from any part of the external surface would be exactly the same. When the radiator was lamp-blacked care was taken to see that a uniform thickness of lampblack was deposited over the entire surface. The thickness was checked by the use of a microscope, thus leaving little chance for an error in the rate of heat lost from the surface exposed to the receiver, in comparison to the heat lost to the walls of the hood in which the entire apparatus was enclosed.

(2) The disk of the receiver was painted with platinum black, while the walls of the hood were lined with fibrous insulating material whose emissivity value was approximately the same as that of the platinum blacked receiver.

(3) The radiometer deflections are dependent on the temperature of the cold side of the junctions. The temperature of the cold junctions increases as the temperature of the radiator and the heat loss from the radiator increases. However, the exact temperature of the cold junctions was measured at the time the deflections were taken, and the true temperature of the receiver could then be determined from the number of junctions in series.

[11] Supervising Engineer, Fuels Section, Pittsburgh Experiment Station, U. S. Bureau of Mines.

The emissivity values were thus calculated from the true temperature of the radiator and the true temperature of the receiver.

(4) In the preliminary experiments, the receiver was provided with a water-cooled enclosure. However, the water temperature could not be maintained constant to closer than 0.1 deg. fahr., and continually rose and fell within that range owing to the operation of the thermostat. Owing to the large number of junctions in the receiver, a variation of 0.1 deg. fahr. causes considerable variation in the deflections. The final experiments were run without the water-cooling as it was found that the temperature of the hood could be held much closer than the water-cooled enclosure could be held. As mentioned previously, the radiator had full exposure to approximately black-body conditions. In any event the area of the radiator was insignificant in comparison to the area of the walls of the hood, and the amount of energy reflected back from the walls to the receiver would be proportional to the ratio of the receiver area to the hood area; and when we consider that the walls have a total reflection of only about 2 per cent and dividing this 2 per cent by the ratio of the receiver area to the wall area the energy received back would be far below 0.01 per cent. In fact, the hood walls could have been lined with polished silver without affecting the accuracy of the experiment to any great extent.

(5) The steel surface used in the emissivity tests was identical in emissivity value to that of the steel pipes, as both were later checked and both were considerably oxidized.

The author appreciates the fact that Mr. Nicholls' discussion is not in the nature of a criticism of the results obtained, but is merely to bring out some of the points of the constructional details and experimental procedure. The author feels that the accuracy of the experiments can be summed up by the fact that his tests check almost exactly with the tests by former investigators who have experimentally determined the black-body radiation constant. This constant has been determined by a great many investigators and has also been calculated mathematically, so that there is little doubt that it will ever be changed 1 per cent, no matter how many investigators re-determine it.

In reply to Mr. King, the author is gratified to know that his results have been mainly confirmed by the experiments of the General Electric Company.

The values of 0.80 for black and white lacquer at 100 deg. are not misprints. These values are for lacquers having a glossy surface. At 100 deg. a value of 0.80 was obtained, while at 200 deg. the value had increased to 0.95. This increase is accounted for by the fact that at a temperature of 200 deg. fahr. the lacquers had become oxidized to a considerable extent and had consequently lost most of their glossy finish, and were consequently radiating at almost as high a rate as the flat black lacquer. The results of these tests were included to show that there was a difference in radiating power between a glossy lacquer or paint and a flat lacquer or paint and also that color had no effect on "black-heat" radiation.

The conductivities for lampblack in Fig. 3 are per inch of thickness.

In regard to the emissivity of the steel pipes, the 3-in. and 1-in. pipes were rechecked at the time the radiation tests were conducted and were found to give exactly the same losses as were obtained several years before.

The author cannot agree with Mr. King's statement that Rice gave the exact value of $n = 0.54$ and $K = 2.60$ in his paper, as he nowhere makes this statement in his paper. In fact, Rice gives the impression that $n = 0.5$ and $K = 2.12$ are the more exact values to use, as he states, "The line of slope $n = 1/2$ has been drawn in such a manner as to give most weight to the last 17 points, since the accuracy of determining (B/D) $(\mu C_{p/k})^{1/4}$ is greater for thin films, assuming equal accuracy in determining the watts convection. Thus for $n = 1/2$ we take $K = 2.12$ in.

It seems strange that if Rice knew that the exact values of n and K were 0.54 and 2.60, respectively, he would go to all the trouble to calculate his equations using the values of 0.5 and 2.12. Throughout his entire paper, including the Summary, he uses the value of n as $1/2$. Any one reading his paper would certainly gain the impression that $1/2$ was the value to use for n.

Using 0.54 and 2.60 for n and K results in the following equation: $W_c = 0.000852\ (1/D)^{0.19}\ p^{0.54}\left(\frac{1}{T_{avg.}}\right)^{0.193}\ \Delta t^{1.27}$ which is not exactly the same as Equation (15) but only approximately so.

The author still maintains that Rice's equation for *long* vertical cylinders is not correct as his equation absolutely ignores the effect of diameter.

While Mr. King is right in stating that the last four of Griffith and Davis' cylinders ranged from 1.83 in. to 11.3 in. in height, he entirely neglects the fact that they obtained practically the same heat loss per unit area of cylinders for 3 ft. and 8 ft. heights. From the results of their tests, a cylinder 3 ft. in height can be considered a *long* cylinder as their graph shows that the loss becomes constant at a height of approximately 60 centimeters, or approximately 2 ft.

In regard to the effect of both diameter and height for short cylinders, the author realizes that an equation containing both diameter and height is dimensionally unsound, and he was therefore very careful not to include such an equation in the paper. However, he cannot agree with Mr. King's statement that the combined effect of diameter and height for short cylinders results in an exponent of approximately 0.2, but believes that the exponent for each dimension or height and diameter should be about 0.2 as mentioned in the paper. If this is true, as experimental tests seem to indicate is the case, then the method outlined in the latter part of the paper is mathematically exact.

In regard to long vertical and horizontal cylinders, the author can see no reason why the vertical cylinder should not lose more heat than the horizontal. As mentioned in the paper, actual tests on a 1-in. and a 3-in. pipe proved conclusively that such was the case. The author expects to continue the work on large vertical and horizontal planes and hopes that some reliable data will be obtained on these shapes.

In regard to Mr. Herter's discussion, it will be very hard to apply the results of these tests to refrigeration work, where the pipes and surfaces are covered with frost or moisture of varying extent.

The discussion by Professor Hechler is very timely and interesting and should help to clear up some of the misconceptions on the transfer of heat through air spaces. The author always felt that it was not logical to use two surface resistances in calculating the resistance of an air space. Since the loss of heat through an air space is usually mainly by radiation, it is not logical to use a surface coefficient of 1.34 for both surfaces. This is theoretically unsound, owing to the fact that radiation takes place from the hotter surface to the cooler surface and the amount transmitted is tied up in both surfaces at the same time and cannot be separated.

The calculations of Professor Hechler showing that the resistance of an air space is usually less than 1.00 have been confirmed by tests conducted at Mellon Institute on air spaces of 0.5 in. to 4 in. These tests were conducted for heat flow horizontally across the space and also vertically upward and downward. By the method of tests, it was possible to separate radiation, convection, and pure conduction. These tests indicated that in vertical air spaces less than 1 in. in width there was practically no heat transmitted by convection.

Professor Hechler's table has also been confirmed by Rowley

and Algren,[12] who found that the resistance of vertical air spaces increased with the width of the space up to about $^3/_4$ in. and became practically constant for widths greater than $^3/_4$ in. They also found that for mean temperatures from 20 to 150 deg. fahr. the resistance was always less than 1.00. The resistance of a 1.5-in. air space at 20 and 150 deg. fahr. mean temperature was 0.975 and 0.64, respectively. For a $^1/_2$-in. air space at the same temperature, the resistances were 0.92 and 0.58, respectively. The temperature differences in these tests were greater than 10 deg. fahr. in all cases, and for the highest mean temperatures the temperature differences were as much as 150 deg. fahr. This accounts for the fact that the resistances obtained by Rowley and Algren are somewhat lower than the values calculated by Professor Hechler for 1 and 10 deg. fahr. temperature difference.

In comparing the author's equations with those of Griffith and Davis, a much closer agreement will be found if the fact is considered that Griffith and Davis used the old black-body radiation constant of 16×10^{-10} instead of the latest value of 17.23×10^{-11}, as used by the author. The old value is about 7 per cent lower than the later values.

The Laws of Similarity for Orifice and Nozzle Flows

A Summary of the More Important Theoretical Results of the Author's Twenty Years of Work on the Flow Through Orifices, Nozzles, and Venturi Tubes

By JOHN L. HODGSON,[1] EGGINGTON, BEDFORDSHIRE, ENGLAND

IN 1909 the author commenced a research which had for its objects the establishment of the square-edged orifice[2] placed between two flanges in a pipe line as an accurate secondary standard of flow measurement, and the development of the necessary theoretical relations which would enable the discharge coefficient for an orifice placed between two flanges in a pipe line, a nozzle, or a venturi tube, when calibrated with any one fluid such as water, to be used as a basis for determining the coefficient of discharge Ω when a geometrically similar[3] orifice, nozzle, or venturi tube was used to measure the discharge of any other fluid such as steam, air, or oil. An account of this work as far as it was then developed was published in 1917 in a paper entitled "The Commercial Metering of Air, Gas, and Steam"[4] which was presented to the Institution of Civil Engineers.

The 1917 paper dealt largely[5] with the comparison of air and water calibrations of the same orifice,[6] nozzle, or venturi tube, and Figs. 17, 32, 33, and 35 of that paper gave the results of such tests plotted against an "elastic-flow criterion" (P_2/P_1) and a "viscous-flow criterion" $(V_1d_2W_1/)\mu$.[7] Figs. 32 and 33 of the paper showed the failure of the viscous-flow criterion when there was appreciable expansion of the fluid at the orifice or nozzle, and Fig. 32 predicted the way in which the elastic-flow criterion would break down when the flow conditions were such that viscosity became of major importance.

In the tests carried out prior to the writing of the 1917 paper the author had not been able to work down to very low values of $V_1d_2W_1/\mu$ with either water or air owing to the small "heads" produced when the velocity was small. Fig. 35 of the 1917 paper therefore showed the $\Omega:V_1d_2W_1/\mu$ curve for air and water[8] rising steeply as it approached the origin, though it was obvious from theoretical considerations that when $V_1d_2W_1/\mu$ was zero Ω must also be zero.[9]

An attempt to complete the curve by using extremely sensitive differential pressure-measuring devices having failed on account of the difficulty, with apparatus of the size then used, of holding the flow steady and eliminating small temperature changes for a sufficient time before each point was taken to enable the minute pressure differences available to produce their proper effect, the author finally succeeded in obtaining a complete curve for one orifice by using various mixtures of glycerine and water. This enabled the viscosity to be varied over a large range, and an easily measurable head to be obtained at each discharge. The complete curve down to the zero value of $V_1d_2W_1/\mu$ was first published by the author in April, 1921.[10] Later in the same year a full account[11] of the research by which the curve was obtained was given by W. N. Bond, who had assisted in the work.

In April, 1922, the author published the results of some further tests on orifices and venturi tubes covering a large flow range,[12] and in 1925 he presented a second paper to the Institution of Civil Engineers entitled "The Orifice as a Basis of Flow Measurement."[13] This paper gave the results of many further tests, and also dealt at some length with the theory of orifice discharge, and with the use of flow criteria which enabled the values of the coefficient of discharge obtained at various flows of one given fluid to be used for any other fluid whose viscosity, density, and elastic properties were known. The following paper and its appendixes summarize and bring up to date the theory of orifice and nozzle flow developed in the 1917 and 1925 papers above referred to.

The Types of Flow

Three properties of a fluid, namely, its viscosity, density, and compressibility, affect its flow through an orifice, nozzle, or venturi tube. In the case of fluids such as compressed air or steam at the pressures usually employed, these three properties normally give rise to six main types of flow, the first five of which

---

[1] Messrs. George Kent, Limited, Luton, England.

[2] Since square-edged orifices placed between two flanges in a pipe line are now almost universally used in the measurement of steam flows, it may be of interest to put on record that the first of such orifices was furnished by the author to Mr. Holbrook Gaskell of the United Alkali Company in 1910; this orifice being calibrated by means of water flows.

[3] It should be noted that the "geometrical similarity" should extend to the positions of the pressure holes, to the relative roughness of the walls of the pipe, to the upstream face of the orifice, and to the upstream and downstream conditions if these are irregular.

[4] Minutes of Proc. Inst. C. E., vol. 204, pp. 108–193.

[5] This paper also gives details of the first large compressed-air meters that were evolved. These meters, which were designed in connection with the Rand Air Power Scheme, were required to measure the kilowatt-hours U in the air delivered according to the relation

$$U = (\Omega\phi)K_2N(P_1 - P_2)^{1/3}(P_1^{1/3}\log P_1/K_3)$$

where K_2 and K_3 are numerical constants.

The first of these meters was installed by the author in 1910, and they are still functioning with an overall accuracy of ± 1 per cent. They measure about 400,000,000 horsepower-hours per year.

[6] Gaskell's tests on the relation between water and steam flows (see vol. 197 of the Proc. Inst. C. E.) were based on the author's then unpublished work, as is explained in Appendix 7 of "The Commercial Metering of Air, Gas, and Steam."

[7] The tests made by the author in 1916–17 were the first tests which proved experimentally for water and air that, provided there was no appreciable expansion of the fluid in passing through the nozzle or orifice, the value of the coefficient of discharge depended only upon the value of the viscous-flow criterion $V_1d_2W_1/\mu$. The viscous-flow criterion is very often wrongly called the Reynolds criterion. It was Lord Rayleigh, and not Prof. Osborne Reynolds, who generalized the theorem. (See *Phil. Mag.*, 1892, p. 59; 1899, vol. 48, p. 231; and the Report of the Advisory Committee for Aeronautics, 1909–10, p. 38.) Reynolds simply showed by his experiments that $VcdW/\mu$ (where Vc is the "critical velocity" and d the diameter of the pipe) was constant for all fluids whatever might be their density W or viscosity μ. (See Phil. Trans., 1883, vol. 174, p. 935, and Reynolds' Collected Papers, vol. 2, p. 51.)

Contributed by the Special Research Committee on Fluid Meters and presented at the Annual Meeting, New York, N. Y., Dec. 3 to 7, 1928, of The American Society of Mechanical Engineers.

[8] The values of the abscissas of this curve are incorrect. The multiplier 10^6 should be 10^2, if V_1 and W_1 are measured in f.p.s. units, and μ is measured in c.g.s. units.

follow one another in succession as the difference of pressure across the orifice is gradually increased from zero upward, or as the pressure ratio is gradually decreased from unity toward zero. These six types of flow may be considered to depend on:

1 *Viscosity only* (streamline flow), where the flow is directly proportional to the difference of pressure across the orifice.

2 *Both viscosity and density.*

3 *Density only*, where the effects of changes of viscosity and compressibility are so small as to be inappreciable, and where the flow through the orifice is proportional to the square root of the difference of pressure across it.[14]

4 *Both the density and the law of compression for the gas* under the particular conditions which obtain at the orifice. For this type the equation of the flow is more conveniently expressed in terms of the pressure ratio, than of the pressure difference, across the orifice.

5 *Both the density and the compressibility of the gas.* For this type the flow is directly proportional to the pressure on the upstream side of the orifice and is independent of the downstream

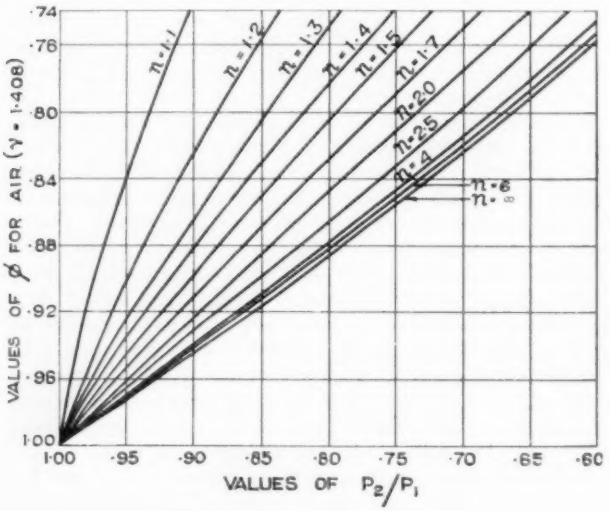

FIG. 1 P_2/P_1 vs. ϕ FOR AIR

pressure, the velocity at the vena contracta being equal to the velocity of sound in the gas at the pressure and density which obtain there.[15]

6 *Density, compressibility, and viscosity.* This type of flow occurs, for example, when the ratio of the respective diameters of the main and orifice is large, and air at low pressure is being measured. In this case the effects of both compressibility and viscosity have to be considered together.

It is only the first of these six types of flow which has a clearly defined and commonly accepted name, viz., streamline or viscous flow. The second type must necessarily involve viscosity with or without turbulence, the third type turbulence, while the last three come within what may be termed the "elastic" region of the flow.

THE DISCHARGE-FORMULA AND COEFFICIENT CURVES

At first glance it would appear necessary to use six different types of formulas to represent these types of flow. The present paper shows that it is possible by means of one formula and two curves of coefficients to represent all six types of flow for any

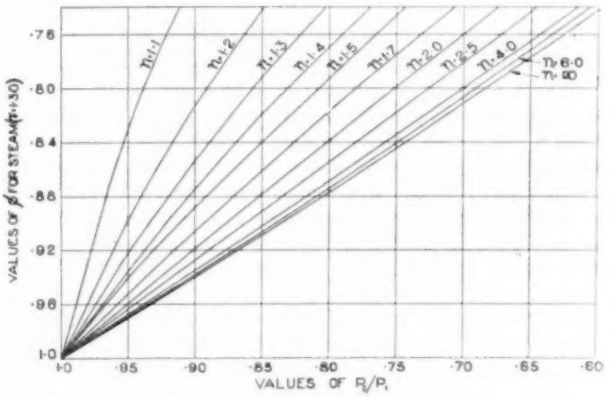

FIG. 1*a* P_2/P_1 vs. ϕ FOR STEAM

orifice of given proportions and situation for any one easily compressible fluid such as air, and for all relatively incompressible fluids such as water. It is further possible to make the results approximately true for all easily compressible fluids, as well as for all relatively incompressible fluids.

Since pressure differences are more easily measured than pressure ratios, the most convenient formula[16] to use from the point of view of practical metering is

$$Q = (\Omega\phi)N[2g(P_1 - P_2)W_1]^{1/2} \quad \ldots\ldots [1]$$

where

$$N = a_1/\sqrt{n^2 - 1} = a_1/\sqrt{(a_1/a_2)^2 - 1} \quad \ldots\ldots [2]$$

and

$$\phi = \frac{\left\{\left(\frac{1}{1-R}\right)\left(\frac{\gamma}{\gamma-1}\right)(1 - R^{(\gamma-1)/\gamma})R^{2/\gamma}\right\}^{1/2}}{\left(\frac{n^2 - R^{2/\gamma}}{n^2 - 1}\right)^{1/2}} \quad \ldots\ldots [3][17]$$

which is the ratio of the adiabatic discharge equation[18] to the liquid discharge equation.

$$Q = \Omega N[2g\,(P_1 - P_2)\,W_1]^{1/2} \quad \ldots\ldots [4]$$

which equation applies without elaboration to flows of the third type.

Values of ϕ for various values of P_2/P_1 and n, calculated for $\gamma = 1.408$ (the value for air) and for $\gamma = 1.3$ (the approximate value for superheated steam), are plotted in Figs. 1 and 1*a*.[19] These curves show that, in the limit when P_2/P_1 is equal to unity, ϕ is also equal to unity. They further show that when n is large

---

[14] For this type of flow, which is the type that most frequently occurs in actual metering, it is only necessary to take account of the density of the fluid. The effects of its viscosity and compressibility may be neglected.

[15] It will be seen later that Flow Types 1 to 5 may be broadly defined as follows:

Type 1, $\sqrt{Q/d_2\mu}$ lies between 0 and 1.5.

Type 2, $\sqrt{Q/d_2\mu}$ lies between 1.5 and 60.0.

Type 3, $\sqrt{Q/d_2\mu}$ is above 60.0, for incompressible fluids.

Type 4, P_2/P_1 lies between 0.96 and the value corresponding to the critical velocity.

Type 5, P_2/P_1 has a value above that corresponding to the critical velocity.

[16] Derived in Appendix No. 2.

[17] Equation [24], Appendix No. 2.

[18] Equation [16], Appendix No. 2.

[19] The following table gives the value of d_2/d_1 corresponding to the values of ϕ, β, and δ plotted in Figs. 1, 1*a*, 17, 18, and 19.

n	1.1	1.2	1.3	1.4	1.5	1.7
d_2/d_1	0.953	0.9125	0.877	0.845	0.8165	0.767
n	2.0	2.25	2.5	4.0	6.0	9.0
d_2/d_1	0.707	0.667	0.6322	0.500	0.408	0.333

(say, greater than 6), the value of ϕ is practically independent of the value of n, but that when n is small, the value of ϕ is very sensitive to the value of n chosen.

As no means exist which enable the exact size of the vena contracta for an orifice in a pipe line to be ascertained (even if any definite vena contracta occurs), the individual values of Ω and ϕ cannot be separated in the case of an orifice for which n is small.[20] As such separation of the values of Ω and ϕ is of theoretical interest only, there is no objection from the point of view of practical metering to plotting values of the combined

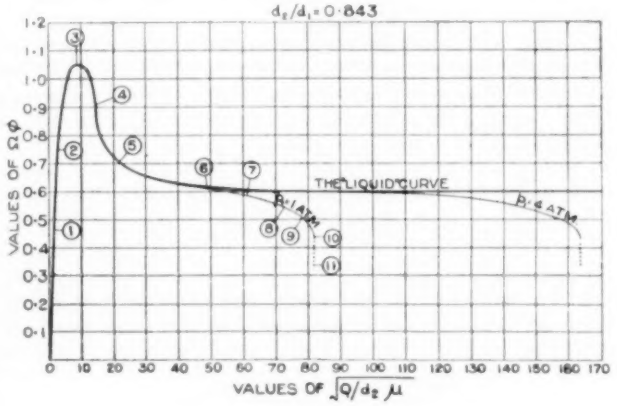

FIG. 2 $\Omega\phi$ VS. $\sqrt{Q/d_2\mu}$ FOR $d_2/d_1 = 0.843$

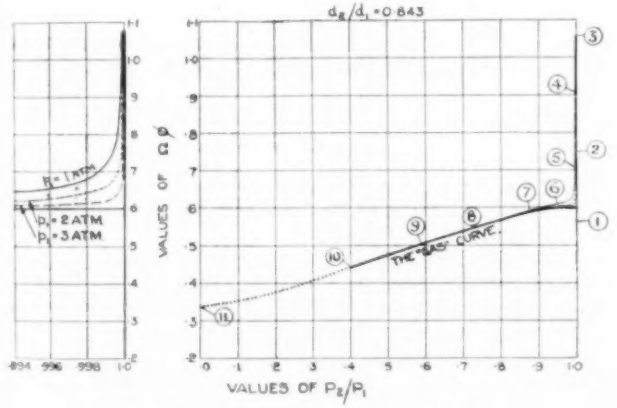

FIG. 3 $\Omega\phi$ VS. P_2/P_1 FOR $d_2/d_1 = 0.843$

coefficients $\Omega\phi$ instead of endeavoring to ascertain the value of Ω itself. For high values of P_2/P_1, where ϕ is practically unity, this procedure is actually equivalent to plotting Ω alone. But, as will be seen on reference to Fig. 1, for the lower values of P_2/P_1, where ϕ is considerably less than unity, the value of $\Omega\phi$ is considerably less than the value that Ω would have, could that value be ascertained. It is for this reason that the value of $\Omega\phi$ falls off as P_2/P_1 is diminished in the curves plotted in Figs. 3 and 6.

If, keeping p_1 equal to 1 atmosphere, an orifice is tested with air (say, a 0.8032-cm. diameter orifice in a 0.952-cm. main for which $d_2/d_1 = 0.843$) for all values of P_2/P_1 between unity and zero, two curves can be plotted. One, the curve numbered 1 to 11 in Fig. 2, connecting $\Omega\phi$ with the viscous-flow criterion[21] $\sqrt{Q/d_2\mu}$; the other, the line numbered 1 to 11 in Fig. 3, connecting $\Omega\phi$ with P_2/P_1. Points in the two curves which represent the same flows are numbered with the same figures.

If now tests are carried out at some higher values of P_1, say, 2, 3, or 4 atmospheres, it will be found that, owing to the diminishing effects of compressibility, portions of these curves will be shifted to the right in both Figs. 2 and 3. (See the curves marked 1 or 4 atmospheres in Fig. 2, and 1, 2, and 3 atmospheres in Fig. 3.) Thus, for every value of p_1 tested, a different set of higher values of $\sqrt{Q/d_2\mu}$ is obtained for the curves shown in Fig. 2, and a different set of higher values of P_2/P_1 for the curves shown in Fig. 3. In a similar way the size of the orifice and the temperature and viscosity of the air will also be found to affect the value of $\Omega\phi$ in both curves.[22]

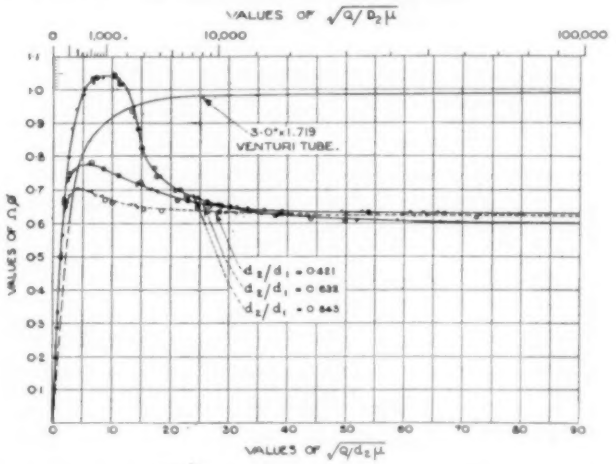

FIG. 4 $\Omega\phi$ VS. $\sqrt{Q/d_2\mu}$ FOR THREE ORIFICES AND A VENTURI TUBE

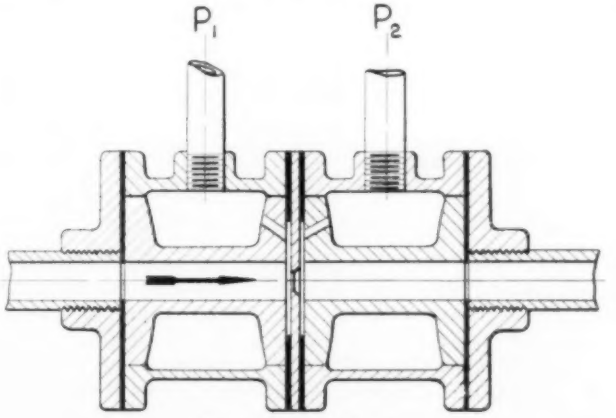

FIG. 5 A TEST ORIFICE

It is possible, however, to express the whole information about the flows through any particular orifice (or group of similar orifices) by means of two curves which, respectively, eliminate compressibility and viscosity effects. This can be done by testing the orifice with a relatively incompressible fluid such as water, or a mixture of glycerine and water, in order to obtain a basis for

[20] Figs. 1 and 1*a* show that, when n is large, the value of ϕ can be obtained with fair accuracy, even though the exact size of the vena contracta, and hence of n, is not known. In such cases a value of Ω can be calculated.

[21] The reason why the viscous-flow criterion, $V_1 d_2 W_1/\mu$, has been converted into $\sqrt{Q/d_2\mu}$ is given in Appendix No. 3 where this criterion is fully discussed.

[22] It is shown in Appendix No. 5 that the general case is to plot the curves connecting values of $\Omega\phi$ and $f(P_2/P_1, \gamma)$ for different values of $P_1 W_1/\mu^2$. Compare also Minutes of Proc. Inst. C. E., vol. 104, p. 190, Fig. 34.

estimating the compressibility effects. The results of such a test are shown by the thick line in Fig. 2, which may be termed the "liquid" curve. For the orifice tested this curve appears to approach to a limiting value of 0.600. If the line $\Omega\phi = 0.600$ is drawn in both diagrams, the distance of the liquid curve above or below this line in Fig. 2 represents the viscosity effect, since the line $\Omega\phi = 0.600$ represents the discharge over that portion of the flow range where the viscosity or compressibility effects are both negligibly small (flow type 3), and the discharge follows the square-root law.

The deducting of this amount at each corresponding point from the curve shown in Fig. 3 gives the thick line, which shows values of $\Omega\phi$ for which the compressibility effects have been separated from the viscosity effects, and which may be called the "gas" curve.

The value of $\Omega\phi$ can be ascertained from the liquid and the gas curves by adding (for the particular values of P_2/P_1 and $\sqrt{Q/d_2\mu}$ chosen) the positive or negative differences of $\Omega\phi$ from the limiting liquid value (0.600) and the thick curves in Figs.

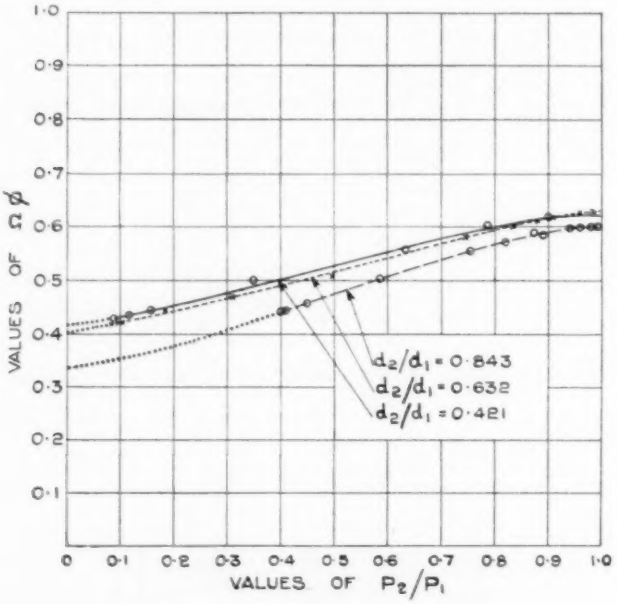

FIG. 6 $\Omega\phi$ VS. P_2/P_1 FOR THREE ORIFICES

2 and 3. Thus, for the points on the thick curves corresponding to the point 6, $\Omega\phi = 0.600 + 0.015$ (from Fig. 2) $+ 0$ (from Fig. 3) $= 0.615$, whereas for the points corresponding to 8, $\Omega\phi = 0.600 + 0$ (from Fig. 2) $- 0.045$ (from Fig. 3) $= 0.555$.

The curves plotted in Fig. 4 show the values of $\Omega\phi$ (i.e., Ω) for incompressible fluids for square-edged orifices of the proportions and sizes described in Appendix No. 8 and illustrated in Fig. 5; while the curves shown in Fig. 6 give the gas curves for these orifices for various values of P_2/P_1.

The extensions of the curves down to $P_2/P_1 = 0$, which are shown in Figs. 2, 3, and 6, have been calculated by the method derived in Appendix No. 6.

Actually the values plotted in Fig. 6 only apply to air. If, however, instead of plotting values of $\Omega\phi$ against P_2/P_1, they had been plotted against[23]

$$\frac{(P_1/P_2)^{(\gamma-1)/\gamma} - 1}{(\gamma-1)\left[1 - \frac{1}{n^2}(P_2/P_1)^{2/\gamma}\right]}$$

[23] See Appendix No. 4, Equation [38].

the "gas" curves determined from this further curve would have been true within small limits for any elastic fluid for which the value of γ was known.[24]

The upper curve in Fig. 7 shows, for various values of d_2/d_1, the limiting values of $\Omega\phi$ when $\sqrt{Q/d_2\mu}$ is large for the liquid curves plotted in Fig. 4; while the lower curve shows the probable limiting value of $\Omega\phi$ when P_2/P_1 = zero[25] for the gas curves plotted in Fig. 6.

Equations are developed in Appendix No. 5, which show that:

1 When measuring gaseous flows at high pressure, the viscosity effects may be neglected unless extremely small pressure differences are being dealt with.

2 The "gas" curve can be determined for the lower values of P_2/P_1 without reference to the liquid curve by testing the orifice with gas at moderately high pressures (say, 4 to 6 atmospheres) or by deducing the results for a high-pressure test from a low-pressure test.

THE VALIDITY OF THE VISCOUS-FLOW CRITERION

The experimental points on the curves in Fig. 4 (covering flow types 1, 2, and 3) which have circles round them were obtained by passing air through the orifice out of or into a liquid-sealed bell of known capacity, and making due allowance for the temperature, pressure, and humidity of the air. The remaining points were taken by means of mixtures of glycerine and water

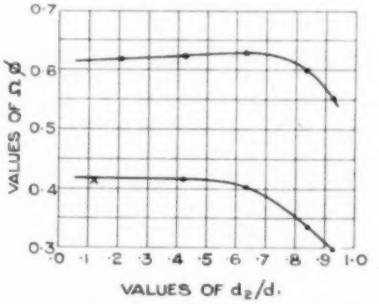

FIG. 7 $\Omega\phi$ VS. d_2/d_1 FOR FOUR ORIFICES

for which the viscosities at the particular temperature worked at were carefully ascertained for each point taken.[26] The great value of the viscous-flow criterion as a basis for coordinating experimental data and for predicting the discharge of geometrically similar orifices is shown by the close agreement between the liquid and gaseous points of the curves plotted in this figure.

It should be remembered, however, that these results were obtained under test conditions, using smooth pipes upstream and downstream of the orifice. If in practice the pipes vary in roughness, the coefficients of discharge for otherwise geometrically similar orifices will not be the same, especially for the smaller pipes where a given change in the roughness produces the greatest effect, which effect results in slightly increasing the value of Ω for flows of type 3, but not appreciably for flow of type 1.

Also coefficient curves such as those shown in Fig. 4 cannot be used to predict the discharge at low rates of flow of such highly viscous oils as tend to jellify when at rest. The actual viscosity of these oils at the instant of discharge depends upon

[24] In any particular case, the variables which may have to be dealt with are n (or d_2/d_1), d_2, Q, W_1 and μ, P_2/P_1 (or $P_1 - P_2$), P_1, and $\Omega\phi$. Curves to suit any particular set of unknowns may be derived by the method given by the author in "Tests on Model Propellers," Proc. Inst. Automobile Engineers, vol. 11 (1917), pp. 270–275.

[25] Calculated by Equation [42], Appendix No. 6.

[26] See Appendix No. 8.

their previous physical treatment, which usually cannot be known with precision.

It is therefore desirable that when these oils have to be measured by means of orifices or nozzles, they should be heated to such a temperature that their viscosity is both sufficiently reduced, and brought to a definite value.

The Importance of Establishing Flow Criteria

The importance, from the point of view of producing accurate meters at a reasonable price, of establishing accurate relations between the discharge of water on the one hand, and such fluids as gas or steam on the other, through similar nozzles and orifices, will be understood when it is remembered that the power required for calibrating any given nozzle or orifice in a closed circuit varies inversely as the square root of the density of the fluid circulating.

Table 1[27] shows that the cost for power when using water as the calibrating fluid is only $^1/_{28.6}$ part of the cost when air at atmospheric pressure is used, and $^1/_{925}$ part of the cost when superheated steam is used. The economy effected in the cost of calibration is actually much more marked than is indicated by the figures in the table, as the capital outlay and the staff required are much less in the case of the more efficient plants.

The table gives, according to the type of calibration plant used, the approximate power in kilowatts required for testing a meter which has a capacity of 6 lb. of air per second at 80 lb. per sq. in. (abs.) and 60 deg. fahr. and which causes a friction drop of 1 lb. per sq. in. in a 6-in. main.

The table has been calculated on the following assumptions:

(*a*) That where the meter is calibrated in a closed circuit, there is an additional fall of pressure of 1 lb. per sq. in. due to friction in the circuit.

(*b*) That the efficiency of the compressing or circulating plant is 0.64.

(*c*) That 20 lb. of steam, if used for the purpose of calibrating meters, would produce 1 kw-hr.

TABLE 1 COMPARISON OF POWER REQUIRED FOR VARIOUS TYPES OF CALIBRATION PLANTS

		Kilowatts	Relative figures
I	Discharging steam at 80 lb. per sq. in. (abs.) and 100 deg. fahr. superheat through the meter and a valve into a condenser	666	925
II	Discharging air at 80 lb. per sq. in. (abs.) through the meter and a valve to atmosphere	598	830
III	Discharging steam at 20 lb. per sq. in. (abs.) and 100 deg. fahr. superheat through the meter and a valve into a condenser	348	483
IV	Circulating air at 14.7 lb. per sq. in. (abs.) in a closed circuit	20.63	28.6
V	Circulating air at 80 lb. per sq. in. (abs.) in a closed circuit	8.82	12.2
VI	Circulating water in a closed circuit	0.721	1.0

Practical Considerations

When using orifices for flow-measurement purposes, an orifice for which d_2/d_1 is less than 0.75 should preferably be chosen, as such an orifice has for liquid flows a practically constant coefficient of discharge over a wide range of flow. Fig. 4 shows that even for the curve $d_2/d_1 = 0.843$, the value of $\Omega\phi$ becomes constant for all values of $\sqrt{Q/d_2\mu}$ above 40. The values of $\sqrt{Q/d_2\mu}$ usually employed in air, steam, and water metering lie between 60 and 900, while the values of P_2/P_1 usually lie between 1.0 and 0.96.

Further, when d_2/d_1 is greater than 0.75, the discharge for any given head becomes much more sensitive to variations in the roughness or in the diameter of the pipe, and to bad upstream or downstream conditions, so that it becomes much more difficult to insure that the test conditions are reproduced in practice with sufficient accuracy.

It is preferable to use a segmental orifice which concentrates the obstructing area symmetrically around the pressure holes instead of increasing d_2/d_1 beyond 0.75, but this arrangement is still sensitive to the sources of error enumerated above. These sources of error are considerably reduced by using the orifice carrier shown in Fig. 8.[28] Here a conical upstream portion, whose widest part is greater and whose narrowest part is less than the

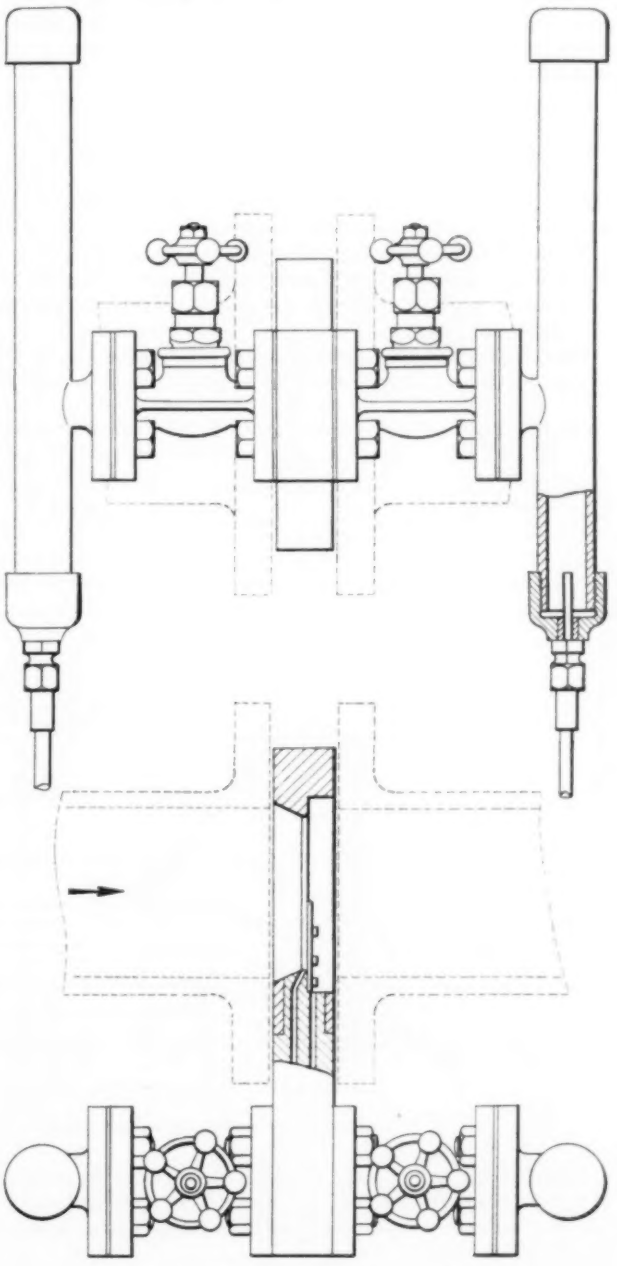

Fig. 8 The Hodgson-Type Orifice Carrier

[27] Reproduced from the author's 1917 paper.

[28] This type of orifice carrier was first put on the market in 1916. It took its present form in 1920. It was first described in the Transactions of the Institute of Naval Architects, p. 185 and Fig. 1, plate 10, vol. lxiv, 1922. Modifications of it have been developed for use in vertical and inclined mains.

nominal diameter of the pipe, eliminates errors due to small variations in that diameter, to slight errors in centering, and to the presence of obstructions such as rivet heads immediately upstream or downstream of the orifice. The drilling of the pressure holes in the orifice carrier also eliminates errors caused by careless drilling and failure to remove the burrs. Fig. 8 shows a segmental orifice plate in place, and illustrates the author's standard-type orifice carrier, cooling pots, and valves for steam measurement.

If the upstream velocity is high, and the value of d_2/d_1 approaches 0.75, the variations in the value of $\Omega\phi$ at the lower velocities should be allowed for as in Appendix No. 7, case 3.

If the value of $\Omega\phi$ used is obtained from tests made on a similar orifice, the pipe upstream and downstream of the orifice should be free from bends, tees, control cocks, etc., unless these were reproduced to scale when the similar orifice was being calibrated.[29] For standard work, a cellular grid should be placed upstream of the orifice to take out the swirl, the presence of which increases the coefficient of discharge.

When measuring gaseous flows at low pressures and at small pressure differences, due allowance should be made for the effects of viscosity as shown in Figs. 3 and 4. If, however, the pressure of the gas is moderately high, say, above 3 or 4 atmospheres, the effects of viscosity may be neglected, and curves similar to those shown in Fig. 6 should be used.

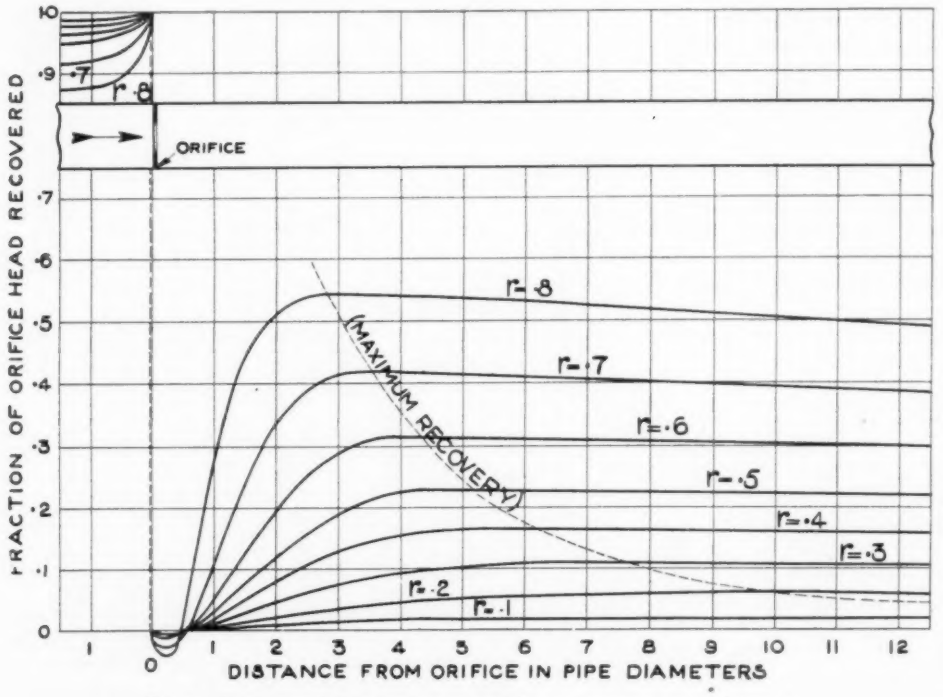

FIG. 9 PRESSURE DISTRIBUTION IN THE NEIGHBORHOOD OF AN ORIFICE

It is not always possible to put the pressure holes in the plane of the orifice,[30] or to make the orifice with square edges or as a circular hole in a thin plate. The relations developed in this paper, however, apply generally to all types of orifices, nozzles, and venturi tubes. They have been found to hold within the limits of commercial accuracy for such diverse fluids as water, thick oil, chlorine, steam, coal gas, etc.; and, whenever it has been possible to make tests with scientific accuracy, they have been found to hold exactly. Such scientific tests have been made by the author on orifices installed in mains from $^3/_8$ in. up to 44 in. in diameter.

A reference to Fig. 9 will show that as a much reduced head is obtained when the downstream pressure hole is drilled in the plane of "maximum recovery," a smaller orifice can be used to produce a given head if the downstream pressure hole is placed in this plane. It is often very tempting to take advantage of this fact when the velocity is high in order to use instruments which will only work up to a standard maximum head. It is, however, undesirable to place the downstream pressure hole in this position unless the orifice can be calibrated in situ, as when this is done the head produced is partly due to the roughness of the pipe immediately downstream of the orifice, and this is not under the control of the designer.

The author prefers the square-edged orifice to any form of nozzle, as the former can be accurately reproduced without difficulty, so that when once the discharge coefficients have been determined for a given orifice, any geometrically similar orifice which has the pressure holes in the same relative position as the original orifice can be constructed and used with confidence. Provided the surface of the upstream face of the orifice is reasonably smooth, the relative roughness of the downstream face does not appreciably alter the value of the coefficient.[31] Monel metal is generally the best material to use, as the squareness of the edge of the orifice does not deteriorate even in superheated steam. The orifice plate must be of sufficient thickness to resist distortion under the difference of pressure (which may include the action of water hammer) to which it will be subjected. Plates thinner than $^1/_{16}$ to $^1/_8$ in. should not be used for accurate work for mains exceeding, say, 3 in. in diameter; and such plates should be beveled off at an angle of 45 deg. on their downstream side so as to leave a thin square edge. A *sharp* beveled edge is both undesirable and unnecessary as it is easily damaged by erosion or impact, and is difficult to measure up accurately.

In the case of orifices used for the measurement of water, a small hole should be drilled through the orifice plate at the top to allow air to pass (see Fig. 13*a*), while in the case of orifices used for the measurement of air or steam the hole should be drilled at the bottom to allow drainage. The area of these holes should be taken as part of a_2.

THE VENTURI TUBE

This device originated in the expanding adjutages used by the

[29] It is, of course, not possible to use an orifice for flow-measurement purposes when the flow is regulated by a valve immediately adjacent to it.

[30] Fig. 9, which is further referred to in Appendix No. 9, shows the way in which the pressure varies along a pipe line in the neighborhood of an orifice. This figure was given in the 1917 paper.

[31] Undue roughness of the upstream face of the orifice slightly increases the coefficient of discharge for flows of type 3, but not appreciably for type 1.

ancient Italians to increase their allowance of irrigation water. It was first developed as one of the most valuable of all devices for the bulk measurement of water by Mr. Clemens Herschel.[32] It consists of a converging upstream cone which produces the fall of pressure required to operate the meter, and a diverging downstream cone which recovers about $^8/_9$ of the fall of pressure produced. The plane of the throat pressure holes is placed between these upstream and downstream cones, and the position of this plane, the angles of the cones, and the changes in the curvatures of the contour of the wall of the tube bridging the cones vary with the experience or fancy of the particular designer.

The curves plotted in Fig. 10 show tests obtained on a number of venturi tubes produced by different makers or experimenters. Some of these tubes have no walls bridging the gap between the upstream and the downstream cones, others have parallel walls;

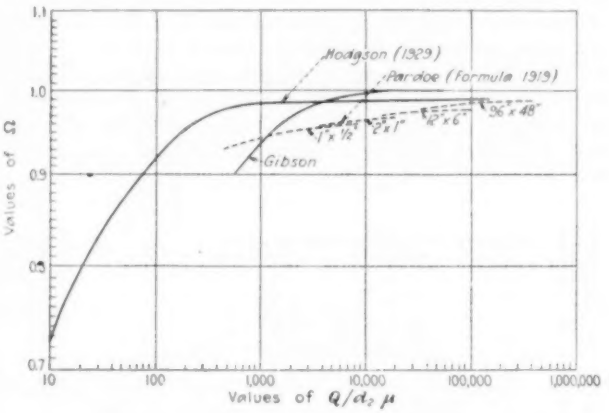

FIG. 10 VARIOUS VENTURI COEFFICIENTS

while others have smooth contours in which there are no abrupt changes of curvature, and in which the throat pressure is taken immediately the maximum convergence of the walls has been effected.[33]

Where the object is to achieve the minimum variation of the coefficient of the venturi tube over the largest possible range of flow, it is obvious that the internal contour of the tube and the plane at which the throat pressure holes are placed must be carefully considered. Even when this is done, it is not possible to obtain with a venturi tube so long a range of fairly level coefficients as it is with an orifice for which d_2/d_1 is small. This can be seen on reference to Fig. 4 on which the test of the Kent 3-in. × 1.719-in. venturi tube which is plotted in Figs. 10 and 11, has been replotted for comparison.[34]

A point of interest in connection with the venturi coefficient is that it is well known that large tubes have higher coefficients than small tubes of the same general proportions. This is apparently contrary to the laws of similarity developed in this paper. It is partly due to the fact that the larger tubes work at higher values of $Q/d_2\mu$. This reason for the apparently higher coefficients of the larger venturi tubes will be seen on reference to Fig. 11.

THE EFFECT OF PULSATIONS IN THE FLOW

If a pulsating *liquid* flow is being measured, the only pulsation error to be allowed for is the *velocity* pulsation error, which is due to the fact that a damped manometer reads the mean of the pressure differences across the orifice; whereas the flow depends upon the square root of these pressure differences. This error should either be reduced to a negligible amount by the provision of air chambers, break-pressure tanks, etc., or of an undamped differential-pressure measuring device which will give equal movements for equal increments or decrements in the flow, and be of sufficiently small inertia to follow the pulsation; the mean of its readings being taken.

It is not usually possible to measure pulsating *gaseous* flows accurately by means of an orifice; as, in addition to the error described above, pressure waves travel up and down the pressure pipes and cause spurious readings. The author has succeeded in eliminating the effect of these pressure waves by splitting up each pressure pipe into several pipes of capillary bore (or the equivalent of this, such as filling the pipes with coarse sand or fine shot) so as to insure that only viscous flows exist in the pressure pipes. This method is not practicable unless the pressure pipes can be kept free from dirt or condensation of moisture (as by heating and filtering).[35]

The best way to measure a compressor discharge with an orifice is therefore to expand the air down to atmospheric pressure (when the pulsations will be damped out by throttling) before inserting the orifice. Alternatively, sufficient receiver capacity and throttling must be introduced between the source of pulsation and the measuring orifice virtually to damp out all the pulsations. In the case of steam flows, the pressure waves in the pressure pipes cause no trouble, as the latter are in this case

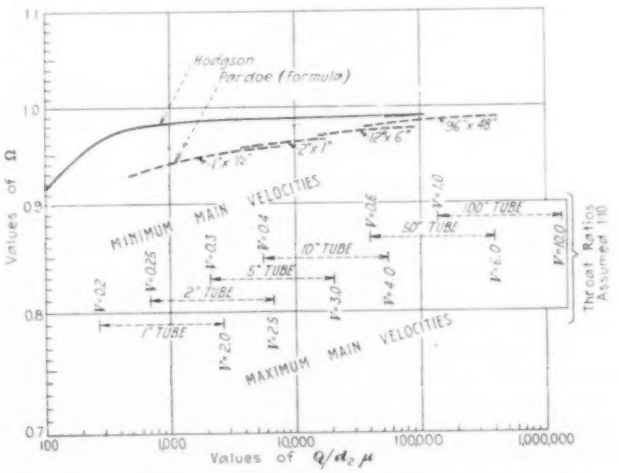

FIG. 11 INCREASE IN THE VENTURI COEFFICIENT WITH d_1

filled with water, which is not appreciably compressed and for which μ is about 60 times that of air; so that viscous damping is obtained without unduly constricting the size of the pipes, and the *velocity* pulsation only has to be dealt with.

It is shown in Appendix No. 10 that, if certain assumptions are made in order to simplify the investigations, the pulsation error due to changes of *velocity* (as distinct from the error caused by pressure waves in the pressure pipes) is the same for the same values of the criterion CFL/ZQ.

Fig. 12 shows a set of pulsation-error curves calculated for a single-cylinder double-acting steam engine at various cut-offs. The units used in that figure are C, cu. ft.; F, cycles per sec.;

[32] See Proc. A.S.C.E., December, 1887.

[33] Compare p. 130 of the author's 1917 paper.

[34] It is of interest to note for purposes of comparison that according to the Stanton and Pannell researches (see Phil. Trans. Royal Soc., vol. 214, pp. 199–224) the flow in smooth pipes of diameter d_2 is definitely viscous for values of $\sqrt{Q/d_2\mu}$ up to 11.2, and is definitely turbulent for values of $\sqrt{Q/d_2\mu}$ down to 15.2.

[35] In meters of the gate and turbine type (described in the author's 1917 paper) the error due to the pressure pulsations does not arise, as there are no pressure pipes.

L, lb. per sq. in.; Z, lb. per sq. in. divided by lb. per cu. ft.; and Q, lb. per sec. These calculated curves indicate that, when the velocity-pulsation error is small, large percentage increases in the value of CFL/ZQ do not affect the pulsation error by more than a fraction of 1 per cent; whereas, when the velocity pulsation error is large, a comparatively small percentage de-

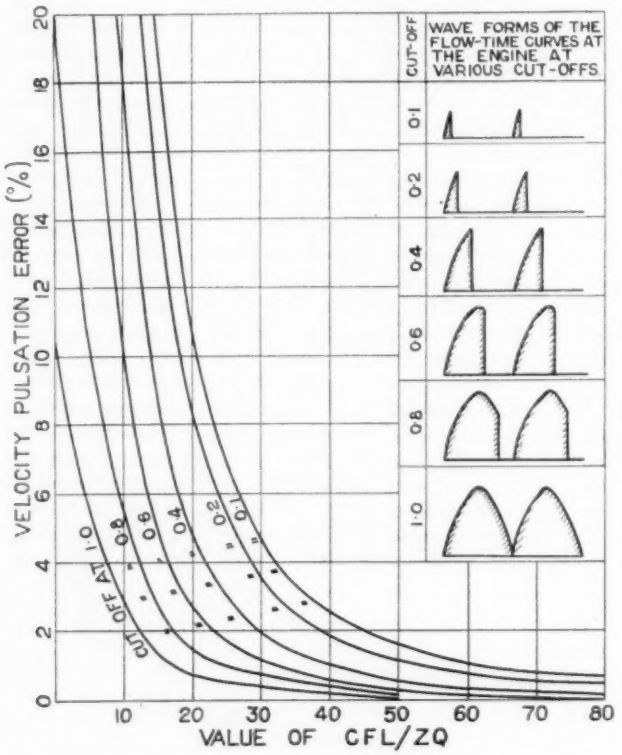

FIG. 12 PULSATION-ERROR CURVES FOR SINGLE-CYLINDER ENGINE

crease in the frequency of the pulsation or the quantity passing may easily affect the pulsation error by 10 or 20 per cent.

Fig. 13 shows how a "velocity-time" wave of square form may be smoothed out, and the meter error reduced to a negligible amount, by increasing the value of CFL/ZQ.

It will be seen from the above investigations that (1) if accurate measurement is required the pulsation error should be kept small, even if allowed for; (2) it is possible to calculate the capacity and loss of pressure required to cause the velocity pulsation error to be small in any particular case; and (3) if the pulsation error is large, and an attempt is made to correct the meter reading by "rating," considerable inaccuracies may be introduced.

Other deductions which follow from a consideration of the CFL/ZQ criterion are:

1 A large meter error may often be reduced to a negligible amount by trebling or quadrupling the value of CL. This may be done by providing for additional throttling, and by putting the meter further from the source of pulsation so as to secure additional capacity. It will be seen that in order to reduce the pulsation error, it is equally efficacious to increase C or L. The energy loss is least when the pulsation is reduced by increasing C, while, if a "capacity" has to be specially provided, the capital cost is greater.

2 If the rate of flow is reduced because the engine slows down (the wave form remaining the same) the meter error will be increased as F and L are reduced, since L falls off more rapidly than Q.

3 Similarly when a steam engine governs, the meter error increases as the flow is reduced. The increase in the error is greatest when the engine governs on the "cut-off" (instead of "on the throttle"), as the wave form is then altered for the worse. If there is an appreciable steam-chest capacity on the engine side of the throttle, the pulsation error may actually be reduced when the engine governs on the throttle.

4 If a throttling orifice which consists of a valve (instead of a fixed orifice) is provided between the metering orifice and the "capacity" and this valve is shut down (either automatically or by hand) as the flow is reduced so that the original L is maintained, the pulsation error will remain constant at all flows, provided that F and Q fall off in the same ratio and the wave form remains the same.

5 It will be seen on reference to Figs. 12 and 13 that if the pulsation error for any flow wave form is large, any small change in the value of CFL/ZQ will cause a large change in the pulsation error, whereas if the pulsation error is reduced to 1 or 2 per cent there may be large variations in the value of CFL/ZQ without causing any appreciable change in the overall error of the meter. It is therefore far better to reduce the pulsation error to a small amount by increasing CFL/ZQ than it is to rate the meter by actual calibration for a large pulsation error.

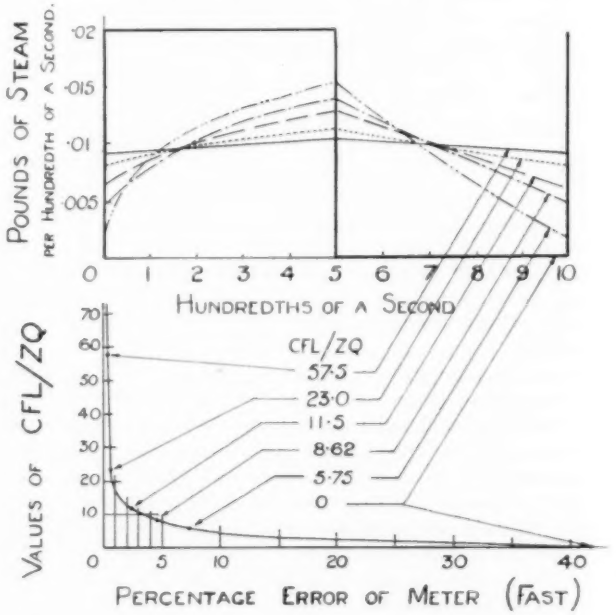

FIG. 13 PULSATION-ERROR CURVES FOR SQUARE WAVE FORM

6 It will be seen that for given values of F, L, Z, and Q the amount that the meter reads fast is (roughly) inversely proportional to C^2, or, for given values of C, L, Z, and Q, to F^2, and so on.

It should be understood that the CFL/ZQ criterion, being deduced from premises which simplify the actual conditions, cannot be used to predict the *exact* pulsation error in any given case, and also that it only holds over a limited range of conditions. For instance, it does not hold when the rate of flow is so great that the loss of pressure L no longer follows the square-root law.

THE CALCULATION OF AN ORIFICE

If a_1 and a_2 are measured in square inches; and h, the observed head in inches of water (0.03609 lb. per cu. in.), is substituted for $(P_1 - P_2)$, Equation [1] becomes

$$Q = 0.127\ (\Omega\phi)\ N\sqrt{hW_1}\ \text{lb. per sec} \quad \ldots\ldots [5]^{35a}$$

N is defined in Equation [2]. It is a term which includes the pipe diameter d_1 and the orifice ratio d_2/d_1 or the ratio s/d_1 as defined in Figs. 14 and 15*a*, i.e., all the actual numerical particulars about the orifice.

The value of W_1, the density of the fluid in pounds per cubic foot at the pressure and temperature which exist at the upstream side of the orifice, will be found for steam or other fluids in the various tables available. It may be calculated for dry air or other gases from the formula

$$W_1 = 2.7\ \Delta p_1/T_1 \quad \ldots\ldots [6]$$

where Δ = specific gravity of the gas relative to dry air at the same temperature and pressure
p_1 = pressure in lb. per sq. in. (abs.)
T_1 = temperature in deg. fahr. (abs.)

In order to ascertain the correct value of $\Omega\phi$ to use, the values of $\sqrt{Q/d_2\mu}$ and P_2/P_1 must be worked out, and the appropriate curves, such as those given in Figs. 4 or 6, consulted.

If the value of P_2/P_1 lies between 1.0 and 0.96,[36] and the value of $\sqrt{Q/d_2\mu}$ is above 60 (which will generally be the case when the orifice is used for metering), and the flow is definitely

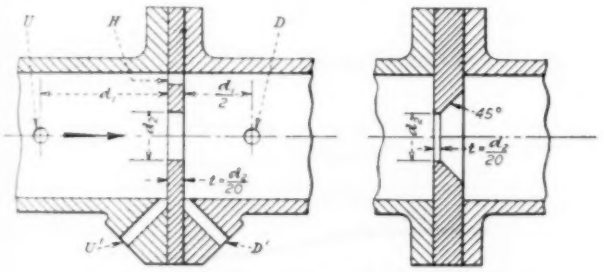

FIG. 13*a* PROPORTIONS OF SQUARE-EDGED ORIFICES

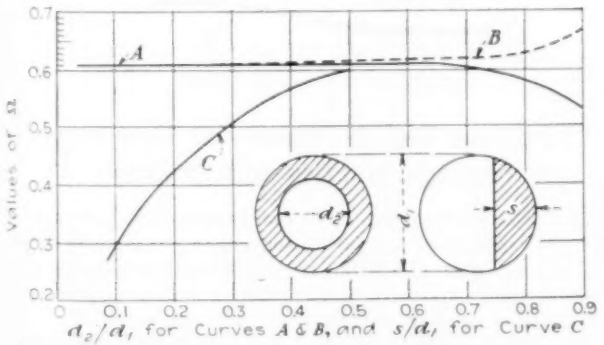

FIG. 14 Ω vs. d_2/d_1 FOR CIRCULAR AND SEGMENTAL ORIFICES

known to be of type 3; a curve similar to the upper curve in Fig. 7 for which ϕ is unity and Ω depends only upon the orifice ratio d_2/d_1 may be used.

Such curves connecting Ω and d_2/d_1 for square-edged circular and segmental orifices in thin plates[36a] placed in 6-in. to 12-in. diameter mains (or with their downstream edges beveled off at 45 deg. as described in the section "Practical Considerations" and illustrated in Fig. 13*a*) with their pressure holes in the plane of the orifice, are shown at *A* and *C* in Fig. 14. The curve when the pressure holes are respectively d_1 upstream and $d_1/2$ downstream of the orifice is shown at *B*.

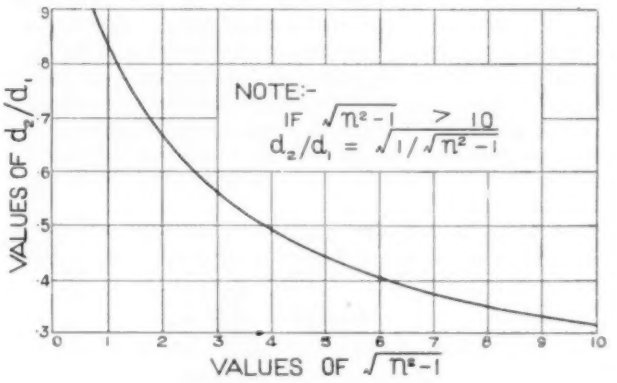

FIG. 15 d_2/d_1 vs. $\sqrt{n^2-1}$

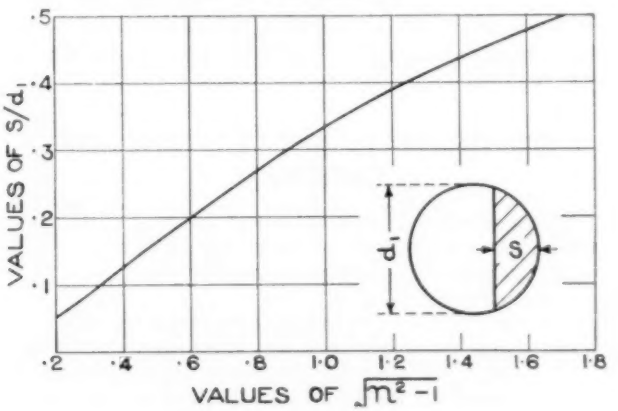

FIG. 15*a* S/d_1 vs. $\sqrt{n^2-1}$

If it is required to find d_2, given the other data, Equation [5] should be rewritten in the form

$$\sqrt{n^2-1} = \frac{0.127\ \Omega\phi\ a_1\sqrt{hW_1}}{Q} \quad \ldots\ldots [7]$$

If ϕ is put equal to unity and an approximate value of Ω (say, 0.61) is assumed, the numerical value of $\sqrt{n^2-1}$ can be calculated from the known data, and the orifice ratio d_2/d_1 (or s/d_1) obtained from curves such as are given in Figs. 15 and 15*a*. If the numerical value of $\sqrt{n^2-1}$ works out to be greater than 10, $\sqrt{n^2-1}$ is equivalent to $\sqrt{n^2}$; i.e., to $(d_1/d_2)^2$. Hence d_2/d_1 can be taken as $\sqrt{1/\sqrt{n^2-1}}$, and obtained by means of a slide rule. The value of d_2 (or s) so obtained will be sufficiently near for all practical purposes. If, however, the curve of coefficients shows that the value of Ω corresponding to the value of d_2 (or s) chosen is appreciably different from 0.61, a more correct value of Ω should be assumed, and a new value of d_2 (or s) worked out.

The value of Ω corresponding to the value of d_2 (or s) actually

[35a] Another form of this equation, derived from Equation [20], is:
$Q = 0.669\ \Omega N(p_1W_1)^{1/2}d$ ..... [5*a*]
$= 0.3250\ \Omega N(p_1W_1)^{1/2}$ ..... [5*b*]
$= 0.3005\ \Omega N(p_1W_1)^{1/2}$ ..... [5*c*]
Equation [5*a*] is generally true; Equation [5*b*] applies to air for which $\gamma = 1.408$, while Equation [5*c*] applies to steam for which $\gamma = 1.130$.

[36] Reference to Fig. 6 will show that if slightly lower values of Ω had been plotted in Fig. 14 so that the deviations of Ω from a mean value had been plus or minus instead of being only minus, it would have been possible to work down to values of P_2/P_1 of 0.9 without appreciable error. It is not generally realized that in those cases where the upstream pressure is more than a few atmospheres, an orifice can be used with reasonable accuracy down to $P_2/P_1 = 0.9$ without correcting for ϕ or its equivalent.

[36a] When the thickness of the parallel part of the orifice does not exceed $d^2/20$.

chosen must, of course, be read off the coefficient curves and substituted in Equation [5] before this is used.

The above procedure, which in special cases can advantageously be shortened by the use of purely graphical methods, is quite general, and enables any set of coefficient curves to be used.

The Units Used

The English system of f.p.s. units has been used throughout the paper, except where otherwise stated. All the values of the viscosity μ have been calculated in these units. In Appendix No. 9 tables of absolute viscosities in f.p.s. units, and the conversion factors between absolute f.p.s. and c.g.s. units are given.[37]

It will be seen from these tables that 10^6 times the absolute f.p.s. unit of viscosity forms a convenient practical unit, and the author has proposed[38] to call this the *megapoisel* (10^6 poisels) after the physician Poiseuille, who first determined the absolute viscosities of fluids.

There seems no reason why engineers who have to work in English units should not also use viscosities tabulated in these units.

Conclusion

In concluding this paper, which is based on the work of twenty years, the author wishes to mention the names of some of those who have been or are his assistants; notably Mr. F. Gray, Mr. W. N. Bond (now Dr. Bond), Mr. E. W. Hovenden, B.Sc., Mr. N. H. Hunt, Mr. H. E. Dall, and Mr. J. R. Ratcliff, B.Sc. Most of these are still with his firm, Messrs. George Kent, Limited, of Luton, England.

Appendix No. 1—List of Symbols and Constants

Q = discharge in pounds per second
P_1, P_2 = pressure in pounds per square foot (abs.[39])
p_1, p_2 = pressures in pounds per square inch (abs.)
R = P_2/P_1
R_1 = the value of P_2/P_1 which satisfies Equation [22]
h, H = heads in inches of water or mercury, respectively (weight of 1 cu. in. of water at 60 deg. fahr. = 0.03609 lb.; weight of 1 cu. in. of pure mercury at 60 deg. fahr. = 0.4893 lb.)
W, W_1 = densities in pounds per cubic foot
A_1, A_2 = areas in square feet
D_1, D_2 = diameters in feet
d_1, d_2 = diameters in inches
a_1, a_2 = areas in square inches
n = $\dfrac{\text{area of upstream}}{\text{area of orifice, or of nozzle throat}}$[40] = a_1/a_2
V_1, V_2 = velocities in feet per second
s = chord width in inches
T, T_1 = temperature in degrees fahrenheit (abs.) = 459.5 + thermometer reading
Ω = discharge coefficient = $\dfrac{\text{actual discharge}}{\text{theoretical discharge}}$[41]
$(\Omega\phi)$ = $\dfrac{\text{actual discharge}}{\text{theoretical discharge not allowing for compressibility effects}}$
Δ = specific gravity of the gas relative to air at the same pressure and temperature
γ = ratio of the specific heats of gases
= 1.408 for air
= 1.3 for superheated steam
g = acceleration due to gravity
= 32.2 ft. per sec. per sec. at Greenwich
β, ϕ, δ, ψ, and α represent terms which are defined in Equations [20], [24], [25], [44], and [47], respectively
μ = viscosity in f.p.s. units
ν = kinematic viscosity = μ/W
Y, K, and K_1 are numerical constants
χ = coefficient of contraction for an orifice
M, L, and T represent the dimensions of mass, length, and time in Appendix No. 11.

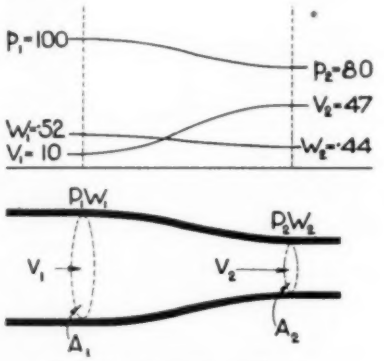

Fig. 16 Diagram of Nozzle

Appendix No. 2—Theory of Discharge Through Nozzles and Orifices[42]

Let A_1 and A_2 in Fig. 16 be two cross-sectional areas in a converging nozzle or in the converging stream lines at an orifice at which the stream lines are parallel and therefore normal[43] to the sections considered; and at which the velocities, pressures, and densities are, respectively, V_1, P_1, W_1, and V_2, P_2, W_2.

If a steady flow be maintained, the same weight of fluid will pass each cross-section in unit time.

If we assume that no energy is supplied or abstracted from the fluid between the two sections, there will be the same energy in the fluid at each section.

[37] To convert $\sqrt{Q/d_2\mu}$ to f.p.s. or c.g.s. units, multiply by $\sqrt{12}$, (=3.464), i.e., by the square root of the number of inches in one foot. The viscous-flow criterion is non-dimensional, and hence has the same value in any *consistent* system of units. For practical purposes it is more convenient to work with d_2 in inches rather than in feet; hence the units in which $\sqrt{Q/d_2\mu}$ is plotted in Figs. 2, 4, 10, and 11.

[38] Proc. Inst. Mining Engineers, 1927, vol. 74.

[39] The suffix "1" is used to denote a point upstream of the orifice, nozzle, or venturi tube; while the suffix "2" is used to denote the plane of the orifice or of the throat of the nozzle or venturi tube, except when otherwise indicated in the text.

[40] In the case of a venturi tube this is usually termed the throat ratio. Note that for orifices, a_2 is to be taken as the area of the actual hole in the plate.

[41] By "theoretical discharge" is meant the discharge calculated on the assumption that there is no loss of energy due to friction, that the stream lines are parallel at the cross-sections between which the differential pressure is measured, that the velocity of flow is uniform across both of these sections, and that compressibility effects have been allowed for by introducing ϕ or its equivalent.

[42] Equations [16], [20], [24], [26], and [22], which involve n, β, ϕ, δ, and relate the maximum values of β to the value of n, respectively, were derived in 1908–9, and first published in the 1917 paper. The methods of evaluating the full St. Venant equation developed in Appendix No. 2 are now almost universally adopted.

[43] The volume passing any cross-section in unit time is only equal to the velocity of the fluid multiplied by the area of the section when the stream lines are perpendicular to the section.

In the case of an incompressible fluid, the velocity at A_2 will be greater than the velocity at A_1 in the ratio of A_1/A_2. This involves an increase in the kinetic energy and a fall in the potential energy of the fluid between A_1 and A_2, since the total energy which passes each of the cross-sections is the same.

If the fluid considered be a gas, the ratio of the increase of velocity will be greater than A_1/A_2, owing to the increase of volume which takes place when the pressure energy, and consequently the pressure falls.[44]

When $(P_1 - P_2)$ is large in relation to P_1,[45] the change in volume which is consequent upon the fall in pressure between A_1 and A_2 causes the discharge formula for gases to differ materially from that which holds for liquids.

In the body of the paper it is shown how to deduce the gaseous discharge from the known liquid discharge through a nozzle or orifice, provided that the velocity of the gas is not sufficiently high to cause the gas to expand appreciably as it passes through the nozzle or orifice.

The general discharge formulas for nozzles[46] and orifices may be derived as follows:

If the energy per pound of fluid is assumed to be constant, the potential energy liberated between A_1 and A_2 will be equal to the kinetic energy gained.

Also, since there is no net gain or loss of energy, the expansion will be adiabatic.

Hence, the potential energy liberated per pound of fluid between A_1 and A_2 is

$$\frac{P_1}{W_1}\frac{\gamma}{\gamma-1}\left\{1-\left(\frac{P_2}{P_1}\right)^{\frac{\gamma-1}{\gamma}}\right\} \quad \ldots\ldots [8]$$

The kinetic energy gained per pound of fluid between A_1 and A_2 is

$$\frac{V_2^2 - V_1^2}{2g} \quad \ldots\ldots [9]$$

Equating,

$$V_2^2 - V_1^2 = 2g\frac{P_1}{W_1}\frac{\gamma}{\gamma-1}\left\{1-\left(\frac{P_2}{P_1}\right)^{\frac{\gamma-1}{\gamma}}\right\} \quad \ldots\ldots [10]$$

For adiabatic expansion

$$\frac{W_2}{W_1} = \left(\frac{P_2}{P_1}\right)^{\frac{1}{\gamma}} \quad \ldots\ldots [11]$$

Now

$$Q = A_1V_1W_1 \quad \ldots\ldots [12]$$

$$= A_2V_2W_2 \quad \ldots\ldots [13]$$

Therefore

$$V_1 = V_2\frac{A_2}{A_1}\frac{W_2}{W_1} = V_2\frac{1}{n}\left(\frac{P_2}{P_1}\right)^{\frac{1}{\gamma}} \quad \ldots\ldots [14]$$

Equation [14] in [10] gives

$$V_2^2\left\{1-\frac{1}{n^2}\left(\frac{P_2}{P_1}\right)^{\frac{2}{\gamma}}\right\} = 2g\frac{P_1}{W_1}\frac{\gamma}{\gamma-1}\left\{1-\left(\frac{P_2}{P_1}\right)^{\frac{\gamma-1}{\gamma}}\right\} \quad [15]$$

Equations [11] and [15] in [13] give

$$Q = A_2V_2W_2 = A_2V_2W_1\left(\frac{P_2}{P_1}\right)^{\frac{1}{\gamma}}$$

$$= \Omega A_2\left[\frac{2gP_1W_1\frac{\gamma}{\gamma-1}\left\{1-\left(\frac{P_2}{P_1}\right)^{\frac{\gamma-1}{\gamma}}\right\}\left\{\frac{P_2}{P_1}\right\}^{\frac{2}{\gamma}}}{1-\frac{1}{n^2}\left(\frac{P_2}{P_1}\right)^{\frac{2}{\gamma}}}\right]^{1/2} \quad \ldots [16]$$

This is the general discharge formula required; where Ω is an experimental discharge coefficient introduced to allow for slight errors in size and faults in manufacture, the formation of a vena contracta in the case of orifices, and the effects of viscosity and of deviations from Boyle's law.

The actual volume passing (measured at P and T, and W) may be obtained from the relation

$$C = Q/W \quad \ldots\ldots [17]$$

Equation [16] being cumbersome to use, its evaluation may be simplified by combining it with the simpler formula obtained on the assumption that the fluid is incompressible, and that W is constant.

To derive this formula, the loss of potential energy is equated to the gain of kinetic energy per pound of fluid between A_1 and A_2, thus:

$$\frac{P_1 - P_2}{W_1} = \frac{V_2^2 - V_1^2}{2g} = \frac{V_2^2 - \left(\frac{V_2}{n}\right)^2}{2g} = \frac{V_2^2}{2g}\left(1-\frac{1}{n^2}\right)$$

Therefore

$$V_2 = \left\{(P_1 - P_2)\frac{2g}{W_1}\frac{n^2}{n^2-1}\right\}^{1/2} \quad \ldots\ldots [18]$$

Inserting Equation [18] in [13] and multiplying Equation [13] by Ω, we have

$$Q = \Omega A_2\left[(P_1 - P_2)\,2gW_1\frac{n^2}{n^2-1}\right]^{1/2} \quad \ldots\ldots [19]$$

This is the approximate equation corresponding to Equation [16]. Combining Equations [16] and [19], we have, after reduction,

$$Q = \Omega A_2\left[\frac{2gn^2}{n^2-1}P_1W_1\right]^{1/2}[\beta] \quad \ldots\ldots [20]$$

$$\text{where } \beta = \left[\frac{\frac{\gamma}{\gamma-1}\left\{1-R^{\frac{\gamma-1}{\gamma}}\right\}\{R\}^{\frac{2}{\gamma}}}{\frac{n^2-R^{2/\gamma}}{n^2-1}}\right]^{1/2} \quad \ldots\ldots [21]$$

and

$$R = P_2/P_1 \quad \ldots\ldots [21a]$$

Equation [20] enables Q to be calculated in terms of P_1 and P_2/P_1. It is the most suitable equation to use for high-velocity discharges.

The curves connecting P_2/P_1 and β for air discharge ($\gamma = 1.408$) and for superheated steam discharge ($\gamma = 1.3$) are plotted for various values of n in Figs. 17 and 18.

Upon reference to Equation [21], it will be seen that β is a maximum when

$$\frac{\left(1-R^{\frac{\gamma-1}{\gamma}}\right)(R)^{2/\gamma}}{n^2-R^{2/\gamma}}$$

is a maximum, i.e., when

[44] Corresponding changes in the velocity, pressure, and density are shown in Fig. 16. They have been calculated on the basis that $P_1 = 100$, $W_1 = 0.52$, $V_1 = 10$, and $A_1/A_2 = 4$.

[45] Say, when $\frac{P_1 - P_2}{P_1} = \frac{1}{50}$

[46] For the purposes of the discharge formula, which does not deal with recovery of pressure, a venturi tube may be considered as a special form of nozzle.

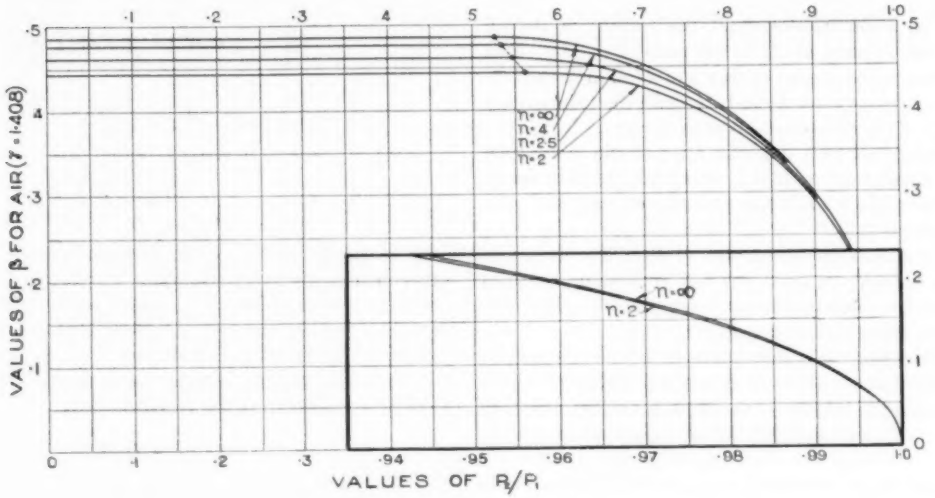

FIG. 17 β VS. P_2/P_1 FOR AIR

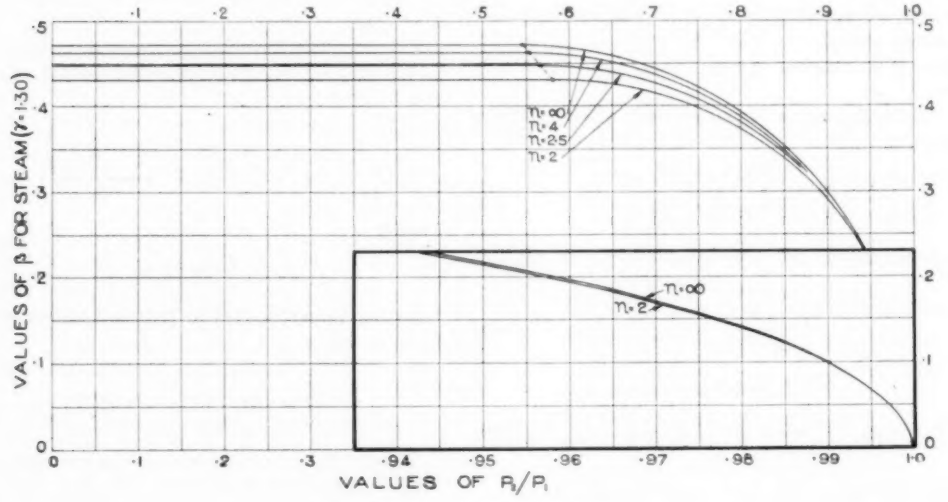

FIG. 18 β VS. P_2/P_1 FOR STEAM

$$\frac{\gamma+1}{R^{2/\gamma}} - \frac{2}{R^{\frac{\gamma+1}{\gamma}}} - \frac{\gamma-1}{n^2} = 0 \quad \ldots\ldots\ldots [22]^{47}$$

and that the discharge, which is proportional to β, apparently diminishes for values of P_2/P_1 which are less than the value of R_1 which satisfies Equation [22]. Actually, however, the pressure at the narrowest section of the issuing jet cannot fall below P_1R_1; as when this velocity is reached the velocity of discharge becomes equal to the velocity of wave propagation at the temperature and pressure which exist at this cross-section, and any external pressure less than P_1R_1 is unable to transmit itself backward along the issuing jet and affect the discharge.

For values of the external pressure less than P_1R_1 the weight discharge therefore becomes directly proportional to P_1, β remaining constant at the value which obtains when $P_2/P_1 = R_1$.

The curves connecting β and P_2/P_1 are therefore drawn parallel

[47] When $n = \infty$, this reduces to $R = \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}} \ldots\ldots [22a]$

and the value of β given in Equation [21] reduces to

$$\beta = \left(\frac{\gamma}{\gamma+1}\right)^{1/2}\left(\frac{2}{\gamma+1}\right)^{\frac{1}{\gamma-1}} \ldots\ldots [22b]$$

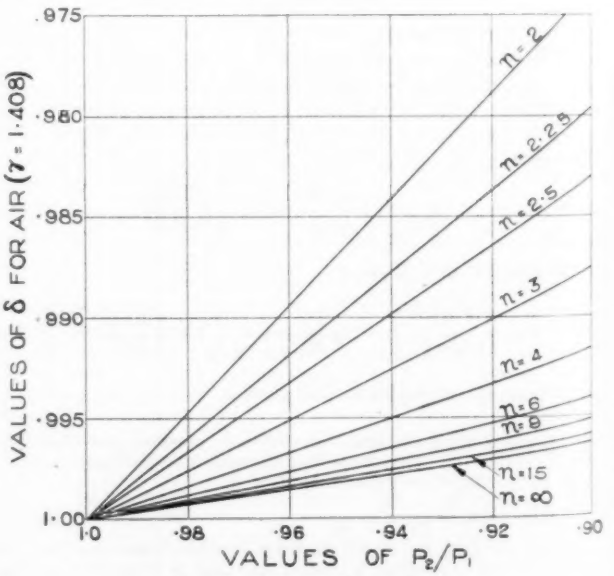

FIG. 19 δ VS. P_2/P_1 FOR AIR

to the P_2/P_1 axis for values of P_2/P_1 which are less than those which satisfy Equation [22].

In most cases that occur in actual metering even the highest velocities which have to be dealt with are comparatively low, so that the value of P_2/P_1 will be found to lie between 0.96 and 1.

Under these circumstances the pressure difference $(P_1 - P_2)$ can be measured much more accurately than the pressure ratio P_2/P_1.

It is therefore necessary to express the discharge Equation [20] in terms of the pressure difference.

This can be done in two ways, the first of which involves what is practically P_1 and $(P_1 - P_2)$ and the second what is practically P_2 and $(P_1 - P_2)$.

These equations, which are easily derived from Equation [20], are:

$$Q = \Omega A_2 \left[\frac{2gn^2}{n^2 - 1} (P_1 - P_2) W_1 \right]^{1/2} [\phi] \quad \ldots\ldots [23]$$

where

$$\phi = \left[\frac{\left(\frac{1}{1-R}\right)\left(\frac{\gamma}{\gamma-1}\right)\left(1 - R^{\frac{\gamma-1}{\gamma}}\right)(R)^{2/\gamma}}{\frac{n^2 - R^{2/\gamma}}{n^2 - 1}} \right]^{1/2} \quad \ldots\ldots [24]$$

and

$$Q = \Omega A_2 \left[\frac{2gn^2}{n^2 - 1} (P_1 - P_2) P_2 \frac{W_1}{P_1} \right]^{1/2} [\delta] \quad \ldots\ldots [25]$$

where

$$\delta = \frac{\phi}{R^{1/2}} = \left[\frac{\frac{1}{R} \cdot \frac{1}{1-R} \cdot \frac{\gamma}{\gamma-1}\left(1 - R^{\frac{\gamma-1}{\gamma}}\right) R^{2/\gamma}}{\frac{n^2 - R^{2/\gamma}}{n^2 - 1}} \right]^{1/2} \quad \ldots\ldots [26]$$

By Equations [21] and [24]

$$\beta = \phi(1 - R) \quad \ldots\ldots [27]$$

Hence, by Equation [26]

$$\beta = \delta[R(1 - R)]^{1/2} \quad \ldots\ldots [28]$$

and

$$\phi = \beta \left(\frac{P_1}{P_1 - P_2} \right)^{1/2} \quad \ldots\ldots [29]$$

$$= \delta \left(\frac{P_2}{P_1} \right)^{1/2} \quad \ldots\ldots [30]$$

Curves connecting P_2/P_1 and ϕ for $\gamma = 1.408$ and 1.3, i.e., corresponding to air and steam discharges, respectively, and connecting P_2/P_1 and δ for $\gamma = 1.408$ are plotted for various values of n in Figs. 1, 1*a*, and 19, respectively.

It will be noticed, on reference to these figures, that when $n > 3$, δ can be taken as unity for values of P_2/P_1 which lie between 0.96 and 1.0; while the corresponding values of ϕ differ considerably from unity.

Equation [25], which involves δ, is therefore in certain cases a more convenient equation to use than Equation [23], which involves ϕ. Equation [23] is however the most generally useful equation to employ as P_1 is usually more constant than P_2.

Appendix No. 3—The Flow Criterion for Viscous Flows

IF IT is assumed that the gaseous or liquid flow through an orifice depends only upon the viscosity μ, the density W, the average velocity V at the orifice, and the diameter d_2 of the orifice, it can be shown by the method of dimensions that the flow conditions are similar for identical values of

$$Vd_2W/\mu \quad \ldots\ldots [31]$$

If $4Q/\pi d_2$ is substituted for Vd_2W, the flow criterion becomes

$$Q/d_2\mu \quad \ldots\ldots [32]$$

The relation between $\Omega\phi$ and $Q/d_2\mu$ can be plotted in various ways, such as directly, or logarithmically. A very convenient way, which has been adopted in most of the figures of the present paper, is to plot $\Omega\phi$ against $\sqrt{Q/d_2\mu}$.[48] This method of plotting causes the liquid curve in the turbulent and the viscous regions (flow types 1 and 3) to be straight lines. It also enables the viscous portion of the curve to be followed right down to zero flow; which logarithmic plotting does not do.

It will be obvious that when the above criterion is applied to gases it can only hold at flows which are so small that compressibility effects are negligible.[49]

It is, however, of interest to compare the values of $\Omega\phi$ and $\sqrt{Q/d_2\mu}$ for liquid and gaseous flows through an orifice over the whole range of values of P_2/P_1 for the gaseous flow.

This has been done at two pressures in Fig. 2.

If

$$2gW_1 = KP_1 \quad \ldots\ldots [33]$$

is substituted in Equation [1] this becomes

$$Q = (\Omega\phi)N\sqrt{(KP_1 - P_2)P_1} \quad \ldots\ldots [34]$$

where

$$\phi = f(P_2/P_1, \gamma)$$

= unity in the limit when $P_2/P_1 = 1$.

It will be seen from Equation [34], and from the curves plotted in Fig. 1 that if P_2/P_1 (and consequently ϕ) differ from unity, the rate of discharge Q will vary with $\sqrt{P_1}$ for given values of P_2/P_1 and $(P_1 - P_2)$. Hence the plotting of corresponding values of Ω and $\sqrt{Q/d_2\mu}$ when the compressibility effects are appreciable is meaningless unless all the results are reduced to some standard pressure P_0 (or density W_0). This can be done by multiplying the value of $\sqrt{Q/d_2\mu}$ obtained by test for any value of $\Omega\phi$ by $\sqrt{P_0/P_1}$ (or, more generally, by $\sqrt{W_0/W_1}$).

The value of $\sqrt{Q/d_2\mu}$ at which the gas curve deviates appreciably from the liquid curve in Fig. 2 shows where compressibility effects begin to be of importance, and the viscous-flow criterion no longer holds.

The straight vertical portions of the constant-pressure curves shown in that figure correspond to flows for which no further diminution in the downstream pressure increases the flow, so that $\sqrt{Q/d_2\mu}$ is constant.

The terminal point of the vertical portions corresponds to the value of $P_2/P_1 = 0$, when $\Omega\phi$ has its minimum value. The method of determining this minimum value is described in Appendix No. 6.

Appendix No. 4—The Approximate Flow Criterion for Elastic Flows

IF IT is assumed that the effects of viscosity are negligible, and that the flow of gas through a constriction of diameter d_2 depends only upon the velocity V_2 (actually it depends upon some value of the velocity between the upstream velocity V_1 and the velocity at the constriction, V_2), the density W_2, and

[48] See footnote 37.

[49] This point was brought out in Figs. 32 and 33 of the 1917 paper.

the adiabatic elasticity P_2 at the constriction, it can be shown by the method of dimensions that the flow conditions are similar for identical values of

$$\frac{W_2 V_2^2}{\gamma P_2} \quad \text{.....[35]}^{50}$$

If $n = \infty$, we have by Equation [15]

$$V_1^2 = 2g \frac{P_1}{W_1} \frac{\gamma}{\gamma - 1} \left\{ 1 - \left(\frac{P_2}{P_1} \right)^{\frac{\gamma-1}{\gamma}} \right\}$$

$$= 2g \frac{P_1}{W_1} \left(\frac{P_2}{P_1} \right)^{1/\gamma} \frac{\gamma}{\gamma - 1} \left\{ 1 - \left(\frac{P_2}{P_1} \right)^{\frac{\gamma-1}{\gamma}} \right\} \text{.....[36]}$$

Since

$$W_2/W_1 = (P_2/P_1)^{1/\gamma}$$

Therefore

$$\frac{W_2 V_2^2}{\gamma P_2} = \frac{W_2}{\gamma P_2} \cdot 2g \frac{P_1}{W_1} \left(\frac{P_2}{P_1} \right)^{1/\gamma} \frac{\gamma}{\gamma - 1} \left\{ 1 - \left(\frac{P_2}{P_1} \right)^{\frac{\gamma-1}{\gamma}} \right\}$$

$$= 2g \frac{(P_1/P_2)^{(\gamma-1)/\gamma}}{\gamma - 1}$$

Hence

$$\frac{\left(\frac{P_1}{P_2} \right)^{(\gamma-1)/\gamma} - 1}{\gamma - 1} \quad \text{.....[37]}$$

may be taken as the flow criterion for elastic flows when $n = \infty$.

Various steam and air tests compared over the elastic flow region on the basis of this criterion have been found to agree within the limits of experimental error.

If n is finite, Equation [37] becomes

$$\frac{\left(\frac{P_1}{P_2} \right)^{\frac{\gamma-1}{\gamma}} - 1}{(\gamma - 1) \left\{ 1 - \frac{1}{n^2} \left(\frac{P_2}{P_1} \right)^{2/\gamma} \right\}} \quad \text{.....[38]}$$

Appendix No. 5—The Relation Between the Viscosity Effect and the Other Factors Affecting Flow

WHEN calibrating an orifice with a gaseous fluid at high values of P_2/P_1, the value of $\Omega\phi$ for any given high value of P_2/P_1 will be found to depend upon the value of P_1 at the time of the test, as shown in Fig. 3.

The value of P_2/P_1 for any given value of $\Omega\phi$ for any value of P_2 can be found from the test results as follows:

It has been shown in Appendix No. 3 that if the compressibility effects are negligible, $\Omega\phi$ and $\sqrt{Q/d_2\mu}$ will have corresponding values.

Hence, $d_2\mu$ may be introduced into Equation [1], which may be rewritten as follows:

$$\frac{P_2}{P_1} = 1 - \frac{\frac{1}{2g} \left(\frac{Q}{d_2\mu} \cdot \frac{1}{\Omega\phi} \right)^2}{\left(\frac{N}{d_2\mu} \right)^2 P_1 W_1}$$

$$= 1 - \frac{\frac{1}{2g} \left(\frac{Q}{d_2\mu} \cdot \frac{1}{\Omega\phi} \right)^2}{\left(\frac{\pi}{4} \right)^2 \frac{n^2}{n^2 - 1} \left(\frac{1}{\mu} \right)^2 \frac{AP_1^2}{T_1}} \quad \text{.....[39]}$$

if a substitution is made for n, and AP_1/T_1 is put equal to W_1. If d_2n, μ, and T_1 are constant, Equation [39] reduces to

$$\frac{P_2}{P_1} = 1 - \frac{\frac{1}{B} \left(\frac{Q}{\Omega\phi} \right)^2}{P_1^2} \quad \text{.....[40]}$$

where B is a constant.

Equation [40] which has been used in calculating the curves marked 1, 2, and 3 atmospheres in Fig. 3 enables the value of P_2/P_1 to be calculated for any particular value of P_1 for each pair of values of Q and $\Omega\phi$ obtained from the test of an orifice. It should be noted that the results plotted apply only to the orifice used. If general results are required, Equation [39] should be used, and the values of $\Omega\phi$ for particular values of n plotted against P_2/P_1 or $f(P_2/P_1, \gamma)$ for various values of $P_1^2/\mu^2 T_1$ or $P_1 W_1/\mu^2$.

In a similar way it can be shown that for liquid flows general results for any particular value of n can be expressed by plotting the relation[51] between Ω and $(P_1 - P_2)$ for various values of

$$(W/\mu)^2 \quad \text{.....[41]}$$

Equation [40] shows that for given values of Q and $\Omega\phi$, P_2/P_1 approaches unity as P_1 is increased. This indicates:

1 That when measuring gaseous flows at high pressure, the viscosity effects may be neglected unless extremely small pressure-differences are being worked with.

2 That what the author has termed the gas curve can be determined for the lower values of P_2/P_1 without reference to the liquid curve by testing the orifice with gas at moderately high pressures (4 to 6 atmospheres), or by deducing the results for a high-pressure test from a low-pressure test by means of Equation [39].

Appendix No. 6—Extrapolation of the $\Omega\phi$ vs. P_2/P_1 Curves Given in Figs. 3 and 6

THE author has found experimentally that, when P_2/P_1 for an orifice is small (say, below 0.3 or 0.2), the ratio P_1/Q_1 becomes constant; that is, the weight discharge becomes proportional to the upstream pressure as in the case of a shaped nozzle. If it is assumed that P_1/Q_1 remains constant right down to the limiting value $P_2/P_1 = 0$, it is easy to derive an equation which enables the $\Omega\phi$ vs. P_2/P_1 curve to be completed.

Thus, if Q_1 is put equal to P_1/Y, where Y is the experimentally determined constant value which P_1/Q_1 reaches at low values of P_2/P_1, this value of Q_1 may be substituted in Equation [1], giving

$$\Omega\phi = \frac{1}{YN\sqrt{2g}} \left(\frac{1}{1 - P_2/P_1} \right)^{1/2} \quad \text{.....[42]}$$

$$= \frac{1}{YN\sqrt{2g}} \text{ in the limit when } P_2 = 0 \text{.....[43]}$$

[50] $\frac{W_2 V_2^2}{\gamma P_2} = \left(\frac{V_2}{V_s} \right)^2$, where V_s is the velocity of sound in the medium of density W_2 which exists at the constriction.

[51] Compare case 3, Appendix No. 7.

Appendix No. 7—Use of the Curves Given in Fig. 4 for Measuring the Flow of Viscous Fluids

THE curves given in Fig. 4 can be used for determining the flow of oil or other viscous fluids.

There are three cases:

Case 1. When the value of $\sqrt{Q/d_2\mu}$ is greater than, say, 60, and the flow is of type 3, Formula [1] should be used. The values of $\Omega\phi$ are given in the upper curve of Fig. 7.

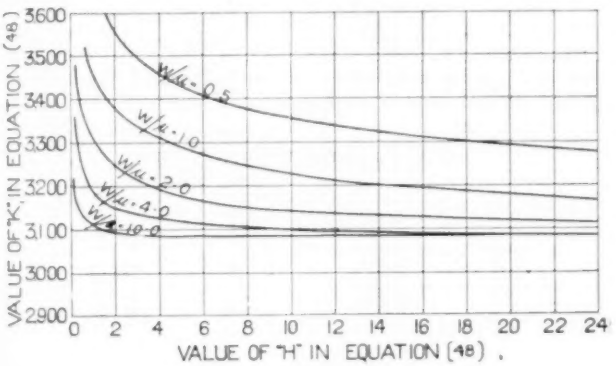

FIG. 20 K vs. W/μ

Case 2. When the value of $\sqrt{Q/d_2\mu}$ is less than, say, 1.5, and the flow is viscous.

It will be seen on reference to Fig. 4, that since the $\Omega\phi$ vs. $\sqrt{Q/d_2\mu}$ curves for each value of d_2/d_1 are straight lines[52] for values of $\sqrt{Q/d_2\mu}$ less than 1.5, it is permissible to write

$$\frac{\sqrt{Q/d_2\mu}}{\Omega\phi} = \psi$$

or

$$Q/\psi^2 d_2\mu = (\Omega\phi)^2 \quad \ldots\ldots [44]$$

where ψ is a constant whose value depends upon the slope of the particular line considered.

But by Equation [1]

$$(\Omega\phi)^2 = Q^2/2gN^2(P_1 - P_2)W_1 \quad \ldots\ldots [45]$$

Equating Equations [44] and [45], we have

$$Q = 2g\left(\frac{N}{\psi}\right)^2 \frac{(P_1 - P_2)W_1}{d_2\mu} \quad \ldots\ldots [46][53]$$

The values of ψ for various values of d_2/d_1 for orifices similar to the orifice used in these tests (which were obtained by plotting to an enlarged scale the data on which the right-hand end of the curves shown in Fig. 4 are based), are given in Table 2.

TABLE 2

d_2/d_1	ψ
0.0515	5.7
0.4210	6.5
0.6320	7.5
0.8340	8.7

Case 3. When the value of $\sqrt{Q/d_2\mu}$ lies between, say, 1.5 and 60, and the flow is of type 2.

In any actual test in which an orifice is used to determine the flow, the quantities which are observed are: the orifice-head, the viscosity, and the density. Hence the simplest procedure is to plot values of α in the equation

$$Q = \alpha\sqrt{(P_1 - P_2)} \quad \ldots\ldots [47]$$

(where α is the value of $(\Omega\phi)N\sqrt{2gW_1}$) for the particular orifice used and for the particular rate of flow passing) against $(P_1 - P_2)$ for various values of W/μ.

An alternative method is to plot the curve connecting values of α and $(P_1 - P_2)\ (W/\mu)^2$. In this case only one curve has to be drawn.

Fig. 20 shows, for various values of W/μ, the curves connecting the value of K_1 in the formula

$$D = K_1\sqrt{H/W} \quad \ldots\ldots [48]$$

where D denotes the discharge in pounds per minute, H the head across the orifice in inches of mercury (at 60 deg. fahr.) immersed in oil of specific gravity 0.8, for a 5.23-in. diameter orifice of the type shown in Fig. 5 in a 9-in. main (i.e., an orifice for which $d_2/d_1 = 0.581$).

It should be noted that, since for any particular fluid W/μ varies with the temperature, the values of W/μ plotted in Fig. 20 can be replaced by temperature values. Further, if it is assumed that W is constant over the range of the experiments, K_1 can be replaced by $K_1\sqrt{H}$, i.e., by D. This enables D to be read directly off a group of curves such as Fig. 20, plotted for different temperatures, when H and the temperature are known.

Alternatively, when W is constant, a single curve connecting K_1 and H/μ can be plotted.

Appendix No. 8—Test Methods Used

THE tests on which the results given in Figs. 2, 3, 4, 6, and 7 are based were carried out with a square-edged orifice 0.8032 cm. in diameter and 0.0914 cm. thick, mounted concentrically in mains 0.952, 1.27, and 1.904 cm. in diameter, corresponding to the following values of d_2/d_1 and N:

TABLE 3

Diameter of main, cm.	d_2/d_1	N
0.952	0.843	0.7203
1.270	0.632	0.5526
1.904	0.421	0.5146

The mean diameter of the orifice was measured by means of a microscope fitted with a micrometer attachment, a plug gage being unsatisfactory. The orifice was mounted as shown in Fig. 5 so that an annular gap 0.04 cm. in width was left at each side between it and the ends of the main. The pressure pipes communicated with these gaps. The orifice was beveled off on the downstream side at an angle of 45 deg., and the length of the parallel part was 0.04 cm.

For the water-glycerine tests, the flow circuit consisted of a tank placed 10 ft. above the orifice; a vertical pipe down to the level of the orifice containing a control cock; a horizontal length of main containing the orifice and of the same diameter as the main at the orifice and a short upward vertical length discharging through a curved spout into an open tank which was connected to a pump delivering the discharged liquid back into the upper tank.

The flow was held steady by means of the indications of a manometer tube which was connected to an opening of large bore which was made in the top of the main upstream of the orifice. The temperature of the fluid was taken on the downstream side of the orifice. The rate of flow was measured by being intercepted at the spout for a known time and weighed. The densities of the mixtures of glycerine and water were

[52] Owing to the small scale to which the figure is drawn these lines all seem to coalesce. Actually they are separate.

[53] This equation can be used to determine the viscosity μ or the kinematic viscosity μ/W.

measured by means of calibrated hydrometers, while their viscosity was determined by means of a capillary-tube viscometer. Tubes of several bores were used in the viscometer and each tube was long enough to ensure that the end effects would be negligible.

Both the water-glycerine and the air tests were carried out in buildings so built or so chosen that they had windows only on the north side, so as to keep temperature changes small. Spiral motion of the fluid in the pipe upstream of the orifice was prevented by the use of a cellular grid. One size of orifice, with different pipe diameters, was used throughout the tests, in order that the flow range to be measured should be as small as possible.

Appendix No. 9—Calculation of Head Recovered at an Orifice

THE curves plotted in Fig. 9[54] show, for flows of type 3, how the pressure varies in the vicinity of circular orifices of various orifice ratios. It will be seen that the recovery of pressure is greatest for the large values of d_2/d_1 and that the point of maximum recovery of pressure travels further downstream as the ratio d_2/d_1 is reduced. It is worthy of note that in cases where d_2/d_1 is large, more than half the orifice head is recovered without any special means being taken, such as the fitting of a diverging cone, to effect such recovery.

The reason for this is that the ratio

$$\frac{(V_2 - V_1)^2/2g}{(V_2^2 - V_1^2)/2g} = \frac{\text{head lost in shock}}{\text{head across orifice}} \quad \ldots\ldots [49]$$

diminishes, for a constant value of $(V_2^2 - V_1^2)/2g$, as V_1 is made more nearly equal to V_2, i.e., as the value of d_2/d_1 is increased. V_2 and V_1 are the velocities at the vena contracta and in the main, respectively.

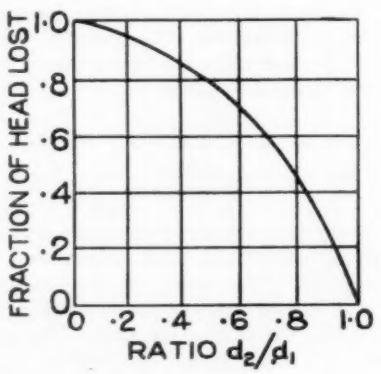

FIG. 21 HEAD LOST VS. d_2/d_1

The fraction of the head recovered by an orifice can be calculated with fair accuracy as follows, if the coefficients of discharge Ω_1 for heads taken between a point one diameter upstream of the orifice and the vena contracta are known:

Fraction of head recovered is

$$\frac{(V_2^2 - V_1^2)/2g - (V_2 - V_1)^2/2g}{(V_2^2 - V_1^2)/2g} = 2V_1/(V_2 + V_1) \quad \ldots [50]$$

But

$$V_2 = \frac{n}{\chi} V_1 \quad \ldots\ldots [51]$$

where χ is the coefficient of contraction for the orifice, and

$$\chi = \frac{\Omega_1 n}{\sqrt{\Omega_1^2 + n^2 - 1}} \quad \ldots\ldots [52]$$

since

$$\frac{\Omega_1}{\sqrt{n^2 - 1}} = \frac{1}{\sqrt{(n/\chi)^2 - 1}}$$

Substituting [51] and [52] in [50], we have, fraction of head recovered is

$$\frac{2\Omega_1}{\Omega_1 + \sqrt{\Omega_1^2 + n^2 - 1}} \quad \ldots\ldots [53]$$

The values of $d_2/d_1, \Omega_1$ as obtained from Fig. 9 and the calculated and experimental values of the fraction of the head recovered are tabulated in Table 4.

TABLE 4 COMPARISON BETWEEN ACTUAL AND CALCULATED HEAD RECOVERED AT ORIFICES

d_2/d_1	Ω_1	Fraction of head recovered	
		Calculated	Experimental
0.8	0.622	0.620	0.619
0.7	0.628	0.500	0.456
0.6	0.622	0.379	0.332
0.5	0.616	0.272	0.234
0.4	0.612	0.180	0.169
0.3	0.609	0.1048	0.105
0.2	0.608	0.0476	0.056
0.1	0.608	0.0122	0.018

Fig. 21 shows the relation between the value of d_2/d_1 (or the equivalent value, $\sqrt{a_2/a_1}$, based on the area ratio) and the fraction of the head lost by an orifice. It is interesting to note that for a simple segmental orifice for which the area ratio is equivalent to $d_2/d_1 = 0.96$, the recovery of pressure is the same as for a venturi tube; and that if the equivalent area ratio of such orifices exceeds 0.96 the recovery of pressure is greater than for a venturi tube.

Appendix No. 10—The *CFL/ZQ* Relation

THE following elementary proof shows that if a meter measures the mean[55] of the difference of pressure across an orifice through which a pulsating flow is passing, the velocity-pulsation error for the cycle will depend upon the numerical value of the pulsating flow criterion CFL/ZQ

where C = the capacity between the points BB and O, in Fig. 22
F = the frequency with which the wave form repeats itself
L = the loss of pressure across the orifice O at the mean flow Q
Z = the product of the specific volume of the steam at the pressure and temperature which exist in the receiver C, and its absolute pressure p_2 (or more exactly $\delta p/\delta W$, where W is the density of the steam at pressure p)
p = the mean absolute pressure in the receiver during the cycle.

A diagram of the arrangement of boiler, receiver, engine, and measuring orifice O is given in Fig. 22, while Fig. 23 shows the wave forms of the flow at BB and O, and the pressure changes in the receiver at various points in the cycle. In this figure l is the loss of pressure across the orifice at any instant.

[54] First published in the Proc. Inst. C. E., vol. 204, p. 132.

[55] The lowest frequency at which the CFL/ZQ relation holds in any particular case depends upon the damping of the meter being such that it is capable of giving a mean value of the differential pressure produced at this lowest frequency. It will be obvious that what is a mere "pulsation" to a heavily damped meter may be a "surge" to one that is lightly damped.

The following assumptions have been made in order to simplify the investigation:

1 That the boiler pressure p_1 is maintained constant
2 That the meter shows the mean value of the differential pressure for the cycle
3 That all the loss of pressure between the engine and the boiler occurs at the orifice O
4 That this loss of pressure varies as the square of the flow, i.e., as Q^2.

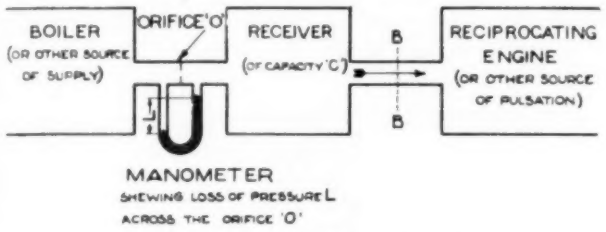

FIG. 22 PULSATING-FLOW DIAGRAM

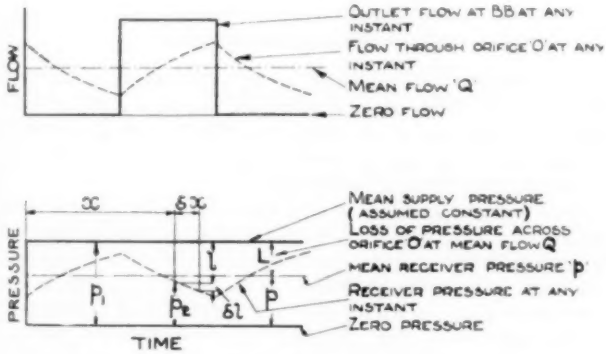

FIG. 23 PULSATING-FLOW FIGURE

The pulsation error will remain the same as long as the ratio of the square root of the mean pressure differences to the mean of the square root of the pressure differences for the cycle remain the same, i.e., as long as

$$\frac{(\Sigma l)^{1/2}}{\Sigma (l)^{1/2}} = \text{constant} \quad \ldots\ldots [54]$$

i.e., so long as δl, the change in head across the orifice O, remains the same for any given fraction of the cycle x, or so long as the ratio of l to L at each point of the cycle remains unaltered.

If S be the weight of steam in the receiver of capacity C at any pressure p_2, then

$$p_2 = \frac{Z}{C} S \quad \ldots\ldots [55]$$

so that if S be the weight of steam lost by the receiver in the time corresponding to the interval δx, then by Equation [55], the corresponding fall of pressure, δl in the receiver will be given by the relation:

$$\delta l = \frac{Z}{C} \delta S \quad \ldots\ldots [56]$$

Now, if Z, F, L, and p are kept constant, and the mean flow Q is doubled by increasing the size of the orifice O, Equation [56] shows that δl will remain constant if C is doubled. Hence if the pulsation error is to remain the same:

$$C/Q = \text{constant} \quad \ldots\ldots [57]$$

If F, L, Q, and p are kept constant, S will be constant, since Q is constant. Hence, by Equation [56], δl and the pulsation error will remain constant if

$$Z/Q = \text{constant} \quad \ldots\ldots [58]$$

If the frequency F be doubled, and Z, L, Q, and p remain the same, only half the flow S will pass through the orifice in the same fraction of the cycle x. Hence if δl is to remain the same, C must be halved, i.e.

$$FC = \text{constant} \quad \ldots\ldots [59]$$

Similarly, if C, L, Q, and p remain the same, Z must be doubled when F is doubled if δl is to remain the same, i.e.,

$$F/Z = \text{constant} \quad \ldots\ldots [60]$$

If Z, F, Q, and p are kept constant, and the loss of pressure across the orifice O at the mean flow Q is doubled by reducing the size of the orifice, δl must be doubled if the $l_1 x$ curve is to retain the same form. That is, ZS/C must be doubled. But, since Z and Q (and hence δS) are constant, this means that C must be halved, i.e., that

$$LC = \text{constant} \quad \ldots\ldots [61]$$

Lastly, if Z, F, L, and Q remain the same, and p is doubled, δS will be the same, since Q is unaltered. Hence, by Equation [56], δl will be unaltered if C remains the same. Hence, the pulsation error is independent of p, although dependent upon Z

$$\ldots\ldots [62]$$

Combining results of Equations [57], [58], [59], [60], [61], and [62], we have:

$$\frac{CFL}{ZQ} = \text{constant} \quad \ldots\ldots [63]$$

Appendix No. 11—Some Notes on Viscosity

THE absolute viscosity of a fluid is defined as *the tangential force per unit area between two parallel planes, unit distance apart in the fluid, which move past one another with unit velocity.*

The dimensions of viscosity are M/LT.

Values of absolute viscosity are usually given in c.g.s. units.

To convert from viscosity in absolute c.g.s. units to viscosity in absolute[56] f.p.s. units, multiply by 0.0672, or by 1/14.88. To convert from viscosity in absolute c.g.s. units to viscosity in gravitational f.p.s. units, multiply by $0.0672/g$ or by $1/14.88g$.

The ratio μ/W or ν is defined as the kinematic viscosity.

The dimensions of kinematic viscosity are L^2/T, and the conversion factor from c.g.s. to f.p.s. units is 0.0010755, or 1/929.03.

TABLE 5 VALUES OF W AND μ FOR AIR AND WATER AT VARIOUS TEMPERATURES, IN ABSOLUTE F.P.S. UNITS[57]

Temperature, deg. fahr.	W Dry air at 30 in. barometer	W Pure water	$10^6 \times \mu$ Air	$10^6 \times \mu$ Water
40	0.07925	62.43	11.72	1037.0
50	0.07770	62.42	11.91	882.0
60	0.07620	62.37	12.09	760.4
70	0.07480	62.30	12.27	659.6
80	0.07345	62.21	12.46	578.8
100	0.07080	62.00	12.83	460.3
120	0.06835	61.71	13.19	378.3
140	0.06610	61.38	13.56	317.7

[56] It is *not* desirable to tabulate viscosities in gravitational or engineers' units, as such values involve the value of g, which varies from place to place.

[57] As stated in the body of the paper, the author proposes to call the unit of viscosity in f.p.s. units the *poisel*, after Poiseuille, who first determined the absolute viscosities of various fluids. The *megapoisel* (10^6 poisels) forms a convenient practical unit.

TABLE 6 VALUES OF μ FOR SATURATED OR SUPERHEATED STEAM[58] AT VARIOUS TEMPERATURES IN F.P.S. UNITS

Rape oil	68	107,000

Discussion

A. A. BARNES.[59] The author's researches over a long period of years in relation to the metering of water, air, gas, and steam are summarized in the present paper and therefore a tremendous amount of detail has been compressed into a small space; this fact makes the paper somewhat difficult to follow at times. Speaking, however, as a water-works engineer, the writer feels that a great future lies before the "orifice gage" for measuring the flow of water in pipes of all sizes in a simple, economical, and straightforward manner and to a degree of accuracy quite exceptional. The criticism, then, is that the formulas are not presented in a form suitable for use from a "water" point of view. No doubt it is necessary and desirable that the questions of viscosity, compressibility, and density of the various elements should be embodied in the general formulas, in order to illustrate the remarkable manner in which air, gas, steam, and water all obey one fundamental law, but, this point having been proved, it seems a pity that the simplified formula for water only has not then been presented.

Existing water meters must work throughout the year over fairly large ranges of temperature, and recording charts take no account of changes in viscosity but are based upon an average density of water of about 62.4 lb. per cu. ft. It is preferable to see the discharge of water represented by the usual unit, cubic feet per second, and, further, to separate in the formula $Q = AV$ the constituents for area and velocity. It is true that those elements are embodied in the final formula, Mr. Hodgson's Equation [5], but they are not evident at first sight. Rearranging that formula for the use of water engineers, the steps are as follows:

$$Q = 0.127\ (\Omega\phi)N\ \sqrt{hW_1}\ \text{lb. per sec.} \quad [5]$$

First divide by W to convert to cubic feet per second, give W the value of 62.4 lb. per cu. ft., and allocate to ϕ its value = 1 for water. Then

$$\text{Discharge} = \frac{0.127\ \Omega N\ \sqrt{h}}{\sqrt{62.4}}\ \text{cu. ft. per sec.}$$

Second, to represent the area of the pipe in the formula, take this from the numerator of the author's coefficient N:

$$N = \frac{a_1}{\sqrt{\left(\frac{a_1}{a_2}\right)^2 - 1}} \quad [2]$$

Hence

$$\text{Discharge} = \frac{a_1 \times 0.127 \times \Omega \times \sqrt{h}}{\sqrt{62.4} \times \sqrt{\left(\frac{a_1}{a_2}\right)^2 - 1}}\ \text{cu. ft. per sec.}$$

Third, from Fig. 14 take the value of Ω to be 0.602, which covers in practice all cases in which the ratio of diameter of orifice to diameter of pipe is not more than 0.7. This gives practically complete contraction and can always be arranged. Hence

$$\text{Discharge} = \frac{a_1 \times 0.127 \times 0.602 \times \sqrt{h}}{\sqrt{62.4} \times \sqrt{\left(\frac{a_1}{a_2}\right)^2 - 1}}\ \text{cu. ft. per sec.} \quad [64a]$$

The formula then becomes very simple:

$$\text{Discharge} = \frac{a_1 \times 0.009678\ \sqrt{h}}{\sqrt{\left(\frac{a_1}{a_2}\right)^2 - 1}}\ \text{cu. ft. per sec.} \quad [64b]$$

in which h = differential head in inches
a_1 = area of pipe in square inches
a_2 = area of orifice in square inches.

The writer made a full-scale orifice experiment on the Elan Aqueduct for Birmingham under ideal conditions, and a short description may not be out of place since it illustrates a practical application of the author's work to sizes and volumes which he himself has not been able to attempt.

On a straight length of a pipe siphon 17 miles long, a brass orifice machined to an exact diameter of 42 in. was pinched between two flanges of a concrete-lined steel pipe, 60 in. in internal diameter. The orifice plate was $^5/_{16}$ in. thick; the opening was machined square for $^1/_{16}$ in. and then chamfered off downstream at an angle of 45 deg. Pressure holes were drilled radially into the 1-in. thick flanges immediately at the orifice, and a brass pipe with an internal diameter of $^5/_{32}$ in. was screwed into each of these, whence copper pipes were led to the gages. The float pipes were taken up to the hydraulic gradient; the water columns therefore gave the differential head without any reduction. The quantity of water passing was controlled by an overflow weir, 19 ft. long, at the inlet to the siphon; this quantity could not vary because the total friction head in the 17 miles of pipe was about 61 ft. The temperature of the water was 52 deg. fahr., and the quantity was steady for 36 hours. The differential head at the orifice was 9.125 in. and the quantity passing was 24,820,000 imp. gal. per day or 46.037 cu. ft. per sec. The discharge was read at submerged rectangular orifices, which had been standardized with similar quantities of water by a series of accurate experiments into a brick-lined reservoir of 100 million gallons capacity.

Computing from the above data with the author's Equation [5] as rearranged in Equation [64b]

$$\text{Discharge} = \frac{2827.44 \times 0.009678 \times \sqrt{9.125}}{\sqrt{\left(\frac{2827.44}{1385.44}\right)^2 - 1}}$$

$$= 46.464\ \text{cu. ft. per sec.}$$

This agrees within 0.9 per cent with the observed reading of 46.037 cu. ft. per sec. and forms a most satisfactory check of the formula far outside the range of the experiments upon which it was based.

The author states that he has made scientific tests on mains up to 44 in. in diameter. It would be important to know if

[58] The viscosity of steam depends only upon its temperature, and is independent of the degree of superheat.

[59] Bartley Reservoir Works, Northfield, Birmingham, England.

any details of such large-scale tests could be given, together with a short description of the methods of calibration which were adopted.

F. N. Connet.[60] The basic invention of the venturi meter by Clemens Herschel in 1887 was followed by the invention and development of the earliest type of registering device by the Builders Iron Foundry of Providence, R. I. Shortly afterward patent licenses for both the meter tube and register were granted to Messrs. George Kent, Ltd., London, England, who revised the mechanical details of the register to conform to European practice. From the first there has been the most helpful cooperation between the two companies, and the experience acquired by each has been at the disposal of the other.

In the early days both companies believed that the most useful field for the venturi meter was that of municipal water works, and this is evidenced by the fact that the average inlet diameter of the first hundred meters made by Builders Iron Foundry was 24 in. This does not include ten 2-in. and 3-in. meters supplied to college laboratories.

It was early found that the capacity range needed for water-works service was about in the ratio 1:6. In other words, the minimum measuring capacity did not have to be less than about one-sixth, or 17 per cent of the maximum. However, the registers actually functioned satisfactorily down to one-thirteenth, or 8 per cent of the maximum.

The exact value of the flow coefficient at extremely low and unused rates was therefore of little practical importance except for small experimental meters where the interest was more academic than useful.

From the very beginning Mr. Herschel encouraged additional experimentation, especially with large meters, and he wisely insisted on following strictly his original venturi-tube proportions so that all subsequent tests would supplement existing data.

One feature of Mr. Herschel's throat design was the short cylindrical portion at the center of which the vent holes were drilled. This cylinder was joined to the upstream cone by a smooth transition curve having a long radius.

This design has been strictly adhered to in the many thousands of meter tubes now in use, and a study of experimental data from many sources does not tempt the Builders Iron Foundry to adopt any modification of the original design. The practice of locating the throat vent holes as nearly as possible at the juncture of the inlet curve and the throat cylinder has some undesirable features because a slight error in location affects the effective throat diameter and appreciably alters the differential, thus making advisable a flow-measurement calibration of each individual meter tube. On the other hand, meter tubes made according to Mr. Herschel's original design prove to be hydraulically identical when machined within measurable tolerances of the intended dimensions. Tests on these tubes having throats even as small as 2 in. in diameter show practically flat coefficients down to about one-tenth of the maximum rate.

Experiments made in America did not fully confirm the author's conclusion that the coefficient curve is less flat when the throat vent holes are at the middle of the cylinder instead of at the end of the transition curve.

It is not easy to obtain extremely accurate readings when the differentials are very low, and even a slight temperature difference in the two small pressure pipes may introduce an error that appears large when plotted upon logarithmic paper where the readings are magnified unduly only at the left-hand edge of the paper. Sometimes a more accurate perspective of values is obtained by plotting tests on the natural scale.

[60] Chief Engineer, Venturi Meter Dept., Builders Iron Foundry, Providence, R. I. Mem. A.S.M.E.

It is a pleasure to study through any of Mr. Hodgson's writings, technical or otherwise, and his ability is shown again in the present paper. He has achieved the art of condensing long and complicated truths into a few lucid sentences.

Ed S. Smith, Jr.[61] The author has long been an able pioneer and authority in fluid-meter theory. The present summary of his work using the method of "similarity" is welcome and most timely as assisting the general acceptance in this country of this method—which is the only rational one—as applied to venturi tubes, nozzles, and orifices. This method has been extensively used in working from models, in airplane and ship design,[62] and has more recently been very valuable in oil heat-exchanger design and pipe-line design in this country. Although widely used abroad, in this country there has been inertia in accepting the method as the basis for fluid-meter coefficients.

The present paper deals primarily with this method and brings out the necessity of using it in connection with fluid meters when measuring the various fluids used in modern industry. Whereas the majority of fluid meters have practically constant coefficients over their operating range, this method shows the actual departures from constant coefficients under certain conditions. The method is invaluable for use with all fluid meters since it definitely establishes the *limits* for constancy of coefficients, thereby serving as the fundamental basis for all fluid metering.

The coefficients presented graphically by the author were, the writer believes, only intended to illustrate the application of this method, and probably would not be recommended by him for use in commercial metering. A paper[63] on metering viscous oils with American venturi tubes presented by the writer introduced this important method of calibrating fluid meters into actual use in this country, although it contained but meager data. The present American practice is better illustrated by the summary[64] prepared by Dr. E. Buckingham, which pre-

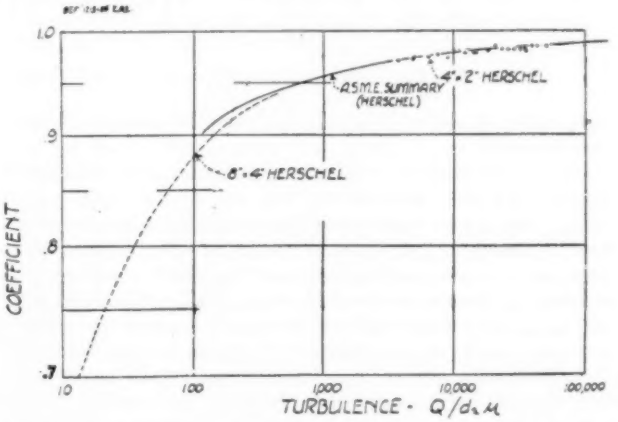

Fig. 24 Coefficient for Venturi Tubes as Designed by Mr. Herschel

sents a large number of calibrations of venturi tubes following the design of Clemens Herschel, which has been standard in America since his invention of this meter. Further data obtained at various hydraulic laboratories for the Builders Iron Foundry on such standard tubes reinforce Dr. Buckingham's

[61] Hydraulic Engineer, Builders Iron Foundry, Providence, R. I. Jun. A.S.M.E.

[62] "The Practical Application of Modern Dynamics to Marine Propulsion," by Stephen E. Slocum, Ph.D., *J. Am. Soc. Naval Engrs.*, vol. 39, pt. 1, Feb., 1927, pp. 1–38.

[63] Trans. A.S.M.E., vol. 45 (1923), p. 67. Ed S. Smith, Jr., "The Oil Venturi Meter."

[64] A.S.M.E. Fluid Meter Report, Part 1, 1924.

summary which, in the opinion of the writer, presents the most accurate available data for these tubes, except for very small sizes (2-in. throat or smaller).

Fig. 24 herewith presents the A.S.M.E. summary of coefficients for venturi tubes as designed by Mr. Herschel. In addition, there are plotted data points obtained by Prof. W. S. Pardoe at the University of Pennsylvania hydraulic laboratory, and witnessed by the writer, upon a standard 4-in. × 2-in. venturi tube, of Mr. Herschel's design, manufactured by Builders Iron Foundry. To give approximately the performance of venturi tubes at much lower Reynolds numbers, there is presented a previously unpublished calibration upon an 8-in. × 4-in. venturi tube, of Mr. Herschel's design, also manufactured by Builders Iron Foundry.

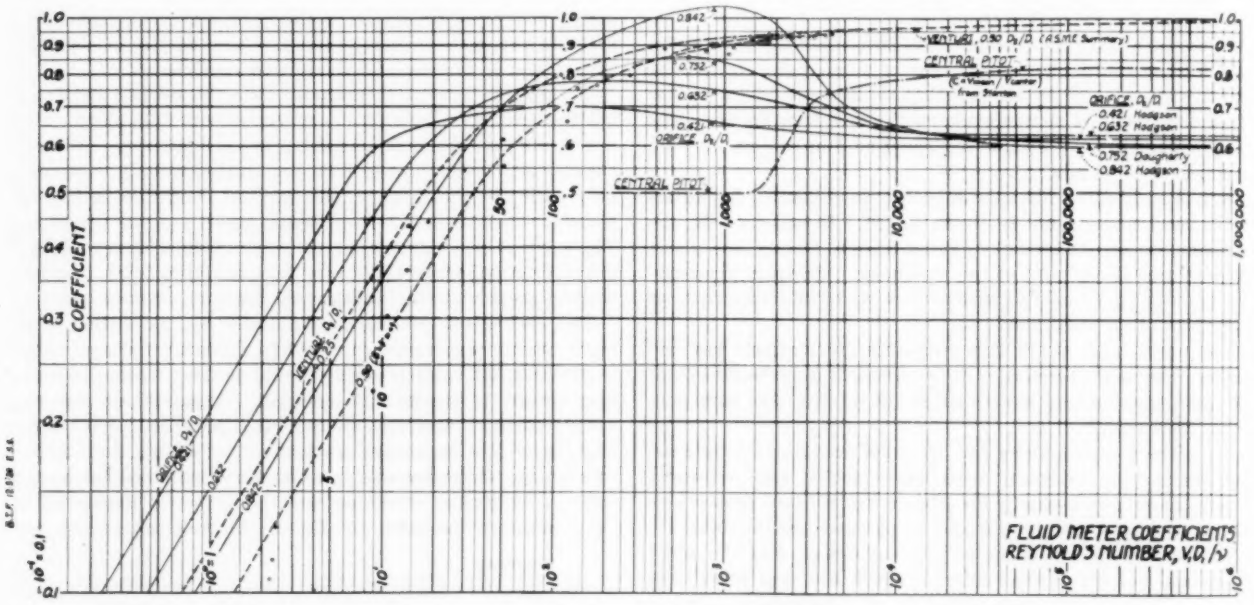

FIG. 25 COEFFICIENT FOR VENTURI TUBES, THIN-PLATE ORIFICES, AND CENTRALLY LOCATED PITOT TUBE

Fig. 25 illustrates the coefficients for venturi tubes, thin-plate orifices with close connections, and a centrally located pitot tube. This shows that the orifice coefficients, for the ratios usually employed, rise at the low rates considerably more than those for the corresponding venturi tubes fall at low rates, considering the change on the percentage basis. (Having smaller loss generally, commercial venturi meters use more differential and have smaller throats than orifice meters for the same rates. Also the orifice size is considerably larger than its effective "throat" or vena contracta.) Further, the coefficients for orifices for various ratios of d_2/d_1 spread out over a wide range when measuring moderately viscous oils; in other words, the venturi coefficient is far better established in general and changes through a much smaller range than orifice coefficients, especially when measuring moderately viscous oils.

As a matter of interest, it will be noted that the centrally located pitot tube has a "flat" coefficient of 0.50 for all values below the lower critical velocity. Although it would seem to form an ideal meter in this range, still it has been found too sensitive to operating difficulties to be reliable in the stream-line region.

In Appendix No. 9, it is noted that some large-ratio orifices may have a smaller loss than some venturi tubes. However, venturi tubes, having substantially the same loss, form reliable meters unaffected by upstream irregularities, while the large-ratio orifices may be highly subject to errors from upstream irregularities.

Logarithmic plotting has the great advantage over square-root plotting of Reynolds numbers that units can be changed as required by merely tracing the coefficients upon shifting the base, whereas the square-root plotting requires recalculation of each test point. Further, on logarithmic paper one can extrapolate the curves as close to zero as necessary since the coefficients show as a straight line on this paper at low Reynolds numbers. This fact is covered in Fig. 25.

In American practice it seems preferable to use the absolute units for both absolute and kinematic viscosities instead of the names "poise" and "poisel," since engineers are not yet generally familiar with those quantities. The kinematic viscosity is much more convenient for oil work than the absolute viscosity. If c.g.s. units are used, it will be found that the kinematic viscosity of water at 68 deg. fahr. is about 0.01 sq. cm. per sec. This is an extremely convenient unit, as the kinematic viscosity of an oil can thus be readily compared with that of water; in other words, the specific kinematic viscosity of the oil is instantly seen when the kinematic viscosity is given as above. Further, the conversion to the f.p.s. unit of square feet per second for kinematic viscosity is obvious, whereas the absolute viscosity involves force and mass units which are less generally agreed upon. The American oil refiner has long been familiar with the conversion from Saybolt seconds to square centimeters per second and this practice is well established in this country. Further, the density in c.g.s. units practically agrees with "specific gravity" for oils and is consequently most convenient for the refiner. For general American practice, the form of Reynolds number which seems most easily used and understood is "turbulence" equals Q/dy, where Q is the rate of flow in U. S. gallons per minute, d is the diameter of the pipe in inches, and y is the kinematic viscosity in square centimeters per second.

J. M. SPITZGLASS.[65] For the last few years the writer has been an ardent reader of Mr. Hodgson's classical papers on the

[65] Mechanical Engineer and Vice-President, Republic Flow Meters Co., Chicago, Ill. Mem. A.S.M.E.

measurement of fluid flow in pipes. When he visited his home last year he told Mr. Hodgson that he would have enjoyed his work much more if the author had given the details pertaining to that work. The present paper is very complete in that respect, and the statements throughout are clear, concise, and to the point. And whether one agrees with the author or not, he knows exactly where he stands and on what his conclusions are based.

The curves in Figs. 2, 3, and 6 are a true picture of the five types of flow involving the three properties of the fluid. The graphical presentation of the quantities is made up partly from experimental work and partly from mathematical computations based on thermodynamic expressions, but the whole picture is so genuine that it is hard to distinguish where experiment ends and theory begins, or vice versa. The matter for discussion is what effect will this paper have upon further developments in the subject of fluid flow.

The author's analysis puts the burden of variation on the existing properties of the fluid. Leaving out the compressibility, which is a matter of mathematical computations, he has varied the viscosity, the density, and the total flow, all of which are properties of the fluid being measured. He has elected to use one size of orifice for all his experiments so that the insertion of the quantity d_2 in his criterion presents a variation in the performance only through the geometrical similarity of the orifice ratio. This is equivalent to advising us that we take care of the properties of the fluid and let the construction of the device be taken care of by geometrical similarity. This geometrical similarity of construction is, in the writer's opinion, not entirely sufficient to ascertain the same results. The roughness, for instance, is a factor which may not be similar for various sizes. In the writer's experiments on the flow of fluids he found that a given percentage in orifice ratio would act differently in different sizes of pipes; therefore he maintains that results obtained from small sizes of pipes will not be duplicated in larger sizes even though the same geometrical proportions are apparently maintained. He does not believe the author is justified in using the results from Fig. 4, which were obtained from tests on pipes less than 2 cm. in diameter, for predicting the flow in a 9-in. main as he does in Fig. 20.

It is to be noticed that in picturing the properties of the fluid and the types of flow the author entirely avoided reference to inertia or the velocity of the fluid, which are really quantities that are included in the criterion. (This omission perhaps is the reason for certain statements which appear contrary to fact.) The writer maintains that the first and most important property in the measurement of fluid is the inertia of the flow or the conversion from pressure to velocity, and vice versa. In most of the devices used the inertia is present in any type of flow. The author refers to the first type as "viscosity only where the flow is directly proportional to the difference of pressure across the orifice." However, even in stream-line flow we cannot neglect the law of conservation of energy, and the increase in velocity through the orifice will require a pressure drop proportional to the square of that velocity in addition to the pressure drop that will overcome the resistance of friction or the effect of viscosity. Therefore even stream-line flow through an orifice is not directly proportional to the difference of pressure across the orifice, because part of that difference is used up to increase the velocity of fluid passing through the orifice. The statement of direct proportionality in stream-line flow has reference only to drop of pressure over a length of pipe where the initial and the final velocity of the flow are the same at both ends.

There are a few other salient points that appeal to the writer in Mr. Hodgson's paper.

1 In his footnote 3, the author warns us that geometrical similarity should be extended to the tap spacing, the roughness of the pipe, the upstream face of the orifice, and the upstream and downstream conditions. To these may be added the thickness of the orifice, and this will give five items for additional experimental investigation.

2 In Figs. 1 and 1*a*, the author shows the correction factor for compressibility of gases and superheated steam. These curves should correspond to those given in Table 1 on page 53 of the Fluid Meter Report as the values of the factor Y for venturi tubes. The writer has compared Equation [3] of the paper with the corresponding Equation [177] of the Fluid Meter Report and found that they read exactly alike, still the figures in Table 1 are somewhat higher than in the author's curves. The shortage of time did not give the writer a chance to investigate the difference. This should be taken up later.

3 In figuring the factors for compressibility the author did not take into consideration the effect of contraction. That is, he treats the orifice the same as a nozzle, which is not strictly correct. In the first paragraph on page 3, he refers to the combined coefficient as a quantity that was obtained directly by experiment. This relates to points 1 to 11 shown on Fig. 3. It would be interesting to have the details of the quantities involved in those points if they were actually carried out by experiment.

4 In Fig. 5 it is seen that the construction of the orifice plate and connections are such as to utilize part of the initial velocity, thereby increasing the amount of the differential pressure corresponding to a given flow. This should be taken into consideration when comparing the results with an orifice plate where the pressures are obtained at points perpendicular to the stream of the fluid.

5 On page 6, at the top of the second column, Mr. Hodgson says, "Such scientific tests have been made by the author on orifices installed in mains from $^{3}/_{8}$ in. up to 44 in. in diameter." The writer would like to ask Mr. Hodgson to give some additional data on some of the scientific tests. He would appreciate having a sketch showing an outline of the method of testing and the actual quantities involved so that it could be compared with other methods and the results of other experimenters.

6 In the third paragraph on page 7, the author calls attention to the fact that the venturi coefficient increases when the size of the pipe is increased for the same general proportions. He says, "This is apparently contrary to the laws of similarity developed in this paper, but it is due to the fact that the larger tubes pass flows at higher velocities." This is equivalent to saying that the blame is not to be put on the increased diameter but on the increased velocity, and, inasmuch as both the diameter and the velocity are equally represented in the Reynolds criterion, the deviation on account of one is just as contrary to the law as the deviation on account of the other.

It is a well-known fact the venturi coefficients increase with the increase in diameter of the pipe, whereas orifice coefficients decrease with increased diameter of the pipe. In the case of the venturi the reduced effect of the friction in larger sizes reduces the total differential for a given flow, and therefore increases the coefficient in the same proportion. In the case of the orifice the frictional resistance has no direct effect on the coefficient because the orifice is practically frictionless. However, when laminar flow is approached the distribution of velocities through the pipe changes considerably, approaching the parabolic form which exists in strictly laminar flow. This condition changes the effect of contraction because the rim of the orifice cuts off comparatively lower velocities. The effect of contraction is reduced, the area of the vena contracta is increased, and therefore the coefficient is increased with the decrease of velocity and diameter.

In the case of the author's tests, embodied in Fig. 6, the effect

appears to be reversed, as the lowest coefficient is shown for the smallest size of pipe (0.952 cm. diameter). This was probably due to the high ratio and the very close connections of the pressure taps. These connections utilize part of the velocity of approach, which is more significant at high ratios. It would be interesting, therefore, to have also the details of the piping, whether it was regular commercial tubing or specially prepared smooth specimen. In our experience small commercial sizes do not give satisfactory results.

The author did not investigate the relation between the theoretical value of ϕ, the compressibility factor, and the corresponding value of this factor as shown by his experiments. As the matter stands now with curves 1 and 1*a* given for reference, one is liable to think that Fig. 6 is made up of the product of experimental hydraulic Ω and compressibility factor ϕ obtained from these curves. For this purpose the writer prepared the

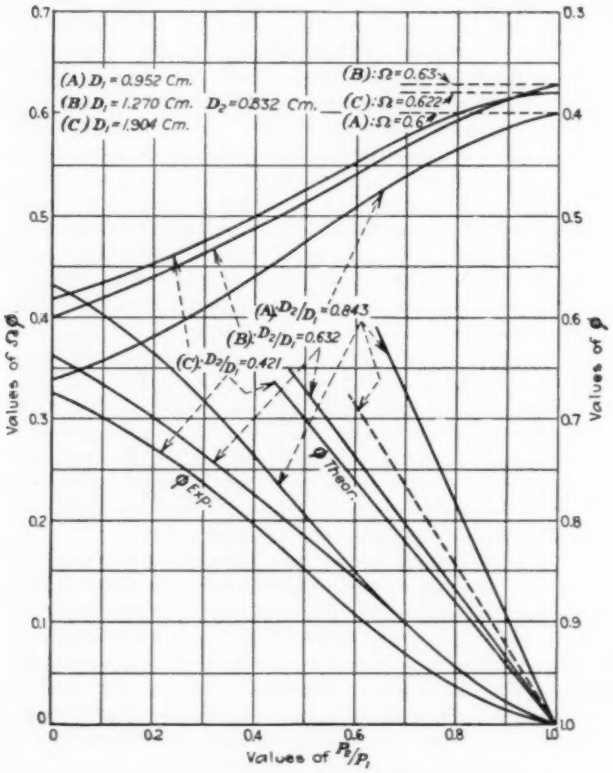

FIG. 26 MODIFICATION OF THE AUTHOR'S FIG. 6

enclosed modification of the author's Fig. 6 (see Fig. 26). This figure shows the comparative values of ϕ theoretical, obtained from Fig. 1, and the experimental obtained when dividing $\Omega\phi$ by the limiting value of Ω. For Case *A*, where the ratio is very high, the value of ϕ is greatly reduced when the contraction is allowed for in the theoretical equation. This is shown by the dotted line which was obtained by correcting the denominator in the author's Equation [3] to read

$$\left(\frac{\frac{n^2}{x^2} - R^{2/\gamma}}{\frac{n^2}{x^2} - 1}\right)^{1/2}$$

instead of

$$\left(\frac{n^2 - R^{2/\gamma}}{n^2 - 1}\right)^{1/2}$$

as given by the author. In Cases *B* and *C* the correction is insignificant, and by correcting Case *A*, as shown, there appears to be an approximate relation of one to two in the difference between ϕ and unity in all cases.

R. E. SPRENKLE.[66] I should like to ask the author if the values of $\Omega\phi$ against d_2/d_1 as shown in Fig. 7 and as obtained with the test orifices installed as in Fig. 5, were duplicated when orifices of the character shown in Fig. 8 were used. An idea as to the magnitude of these differences, if such were found, would be highly useful. Also, is a concentric orifice used with the orifice carrier, and if so how does its coefficient vary from that of the test orifice set up under like conditions of flow?

It is assumed that the pressure connections were made in the plane of the orifice in obtaining the data shown in Fig. 7. If so, how does the author reconcile the perfectly flat curve *a* in Fig. 14 with the upper curve in Fig. 7 which shows an increase of approximately 4 per cent on a flow basis between zero and 0.65 for d_2/d_1?

It is pointed out that various American experimenters have found it inadvisable to damp or throttle the meter pressure pipes, as suggested in appendix No. 10. They also believe from their experiments—notably those of Professor Judd—that the pressure pulsation is greater than the velocity pulsation. It should also be borne in mind that the effect of capacity *C* is at its greatest when it affords an abrupt volume enlargement over the pipe size adjacent to it, instead of a gradual volume enlargement.

F. C. JOHANSEN.[67] In 1928 the writer made a series of experiments, similar to those described in Mr. Hodgson's paper, on the flow of water through diaphragm orifices mounted in pipe lines. The results of the work were expected to be of value mainly in connection with laboratory research, and the scope

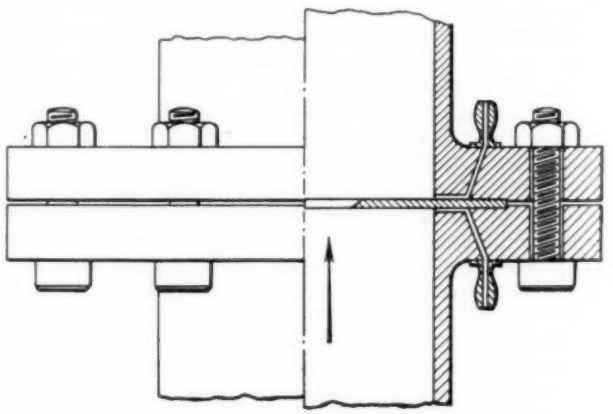

FIG. 27 MR. JOHANSEN'S TEST ORIFICE

of the experiments was therefore restricted to values of Reynolds number below about 50,000. Altogether four sizes of orifice were studied, the diameter ratios being, respectively, 0.2, 0.4, 0.6, and 0.8. The orifice plates were mounted in a smooth brass pipe of 3.2 cm. bore in the manner shown in Fig. 27. The apertures were sharp-edged and beveled at 45 deg. on the downstream side, while the thickness of the plate was arranged to be 0.08 of the orifice diameter in each case. With regard to the situation of the pressure holes for the measurement of discharge coefficient, Mr. Hodgson's practice of arranging these as close as possible to the diaphragm was adjudged to provide the most

[66] Mechanical Engineer, Bailey Meter Co., Cleveland, Ohio. Assoc-Mem. A.S.M.E.

[67] National Physical Laboratory, England.

definite solution of a somewhat controversial feature, and accordingly was followed. It may be remarked that not the least advantage of this location arises from the facility with which the work of different investigators may be compared.

In addition to the determination of discharge coefficients over a range of Reynolds numbers extending downward to flows of a purely laminar type, the writer paid some attention to observations of the pressure gradients upstream and downstream of the orifice, and to variations of these gradients accompanying variations of orifice diameter ratio and rate of flow. For the measurement of the smallest pressures involved, a two-liquid modification of the well-known Chattock tilting manometer was devised, in which carbon tetrachloride (of specific gravity about 1.605) and water were the fluids used. When the meniscus of separation was viewed through a microscope magnifying about 25 diameters and provided with a graticule eyepiece, differential heads could be measured to within $^1/_{1000}$ of a centimeter of water. The maximum head measurable with this gage being about 1 cm. of water, a similar gage, containing mercury in contact with water, was required for the larger flows.

As regards discharge coefficients, four curves similar to those of Mr. Hodgson's Fig. 4 were derived and show good agreement, the interesting phenomenon of maximum coefficients appreciably greater than those which hold over the major portion of the $\sqrt{Q/d_2\mu}$ range being very clearly exhibited. The writer found that his maximum values, plotted against diameter ratio, fell on a smooth curve to contain Mr. Hodgson's three values and one further value due to Dr. Bond,[68] who worked with a

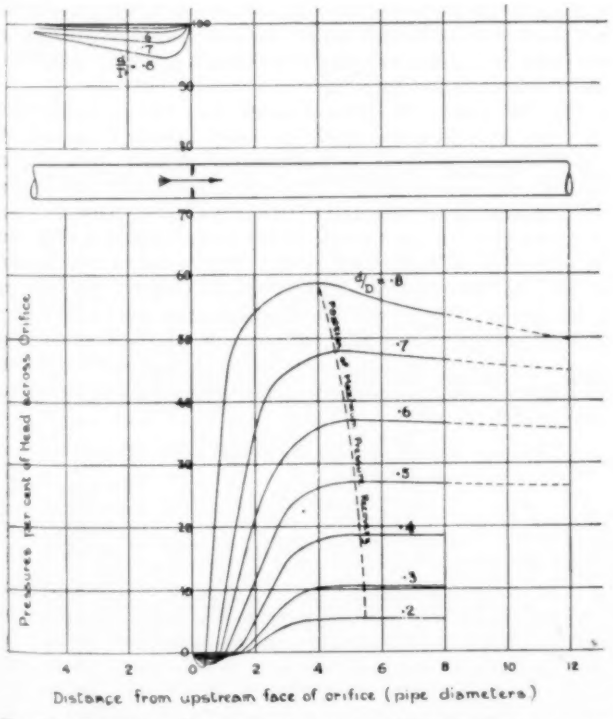

FIG. 28 PRESSURE DISTRIBUTION IN THE NEIGHBORHOOD OF AN ORIFICE IN A SMOOTH BRASS PIPE 3.194 CM. BORE

diameter ratio of 0.0515. Similarly the values of $\sqrt{Q/d_2\mu}$ at which these maxima occur, when plotted against diameter ratio, fall on one curve for all three series of experiments. These large discharge coefficients may possibly be explained to some extent by the consideration that, at the rates of flow for which they occur, the distribution of velocity upstream of the orifice is far from uniform, with the result that the true kinetic head upstream is in excess of that based on the mean flow to an extent greater than that which relates to the jet at the orifice.

In the region of purely turbulent flow, the writer's sharp-edged orifices were found to have discharge coefficients in close agreement with those of Mr. Hodgson, as shown in his Fig. 7, the value of the coefficient increasing from 0.608 at $d_2/d_1 = 0.2$ to 0.624 at $d_2/d_1 = 0.7$.

Mr. Hodgson's pressure-distribution curves in Fig. 9 are mainly confirmed by the writer's experiments, a selection from which relating to Reynolds number 10,000 is reproduced for comparison in Fig. 28. Almost the only feature at variance is the position of the section of maximum pressure recovery, which, for the writer's small-orifice ratios, tended to a limiting distance of about five pipe diameters downstream of the orifice. It should be realized that the broken line indicating these positions in Fig. 28 has been derived from the actual observations of pressure distribution and is much more clearly defined than the shape of the curves of Fig. 28 would appear to warrant. It is thought that the positions of maximum pressure recovery shown in Fig. 28 are correct to about half a pipe diameter. One further feature of the writer's pressure-recovery curves which calls for comment is the pressure gradient just downstream of the maximum, which is appreciably steeper than that which occurs beyond about eight pipe diameters downstream of the orifice. This effect appears most clearly in the curve for diameter ratio 0.8 of Fig. 28. Since completing his experiments the writer has noticed a similar effect in the report of Jakob and Kretzschmer's[69] work on orifices.

The scope of the writer's experiments did not extend to the investigation of the variation of the pressure phenomena near an orifice with the roughness of the pipe line, although it was evident from Spitzglass's work that this variant was of importance—a conclusion which Jakob and Kretzschmer's research has amply confirmed. Mr. Hodgson's present paper is not, of course, concerned with that aspect of the orifice-flow problem, but it would be of interest to learn whether his experience over a wide range of size of orifice meter has enabled him to arrive at any definite conclusions regarding the effect of pipe roughness on discharge coefficient.

G. M. CLARK.[70] The writer has been particularly interested in reading the very valuable contribution of the author to later knowledge on the behavior of the flow of fluids through orifices and nozzles, as they had first met about twenty years ago, when the air meters designed by the author were first put into service for the Victoria Falls & Transvaal Power Company in South Africa for the metering of the supply of compressed air to the gold mines of the Witwatersrand. The sale of this compressed air gives a revenue of about one million dollars a year at a rate that is equivalent to a supply of electric energy at 1 cent a kilowatt-hour. It was therefore important that the meters should secure a high order of accuracy. This was attained at that time with an accuracy of about 1 per cent, and the meters have been in constant service for almost 20 years. These meters are of the venturi type, and their indications are checked at the mines by the purchasers' meters of the weighted-gate type,[71] also designed by the author, and these comparisons show that both groups of meters have continued to exercise their functions with the greatest satisfaction.

At the same period the author first brought out the plate orifice almost in its present-day design, and it was first used

[68] See footnote 11 of Mr. Hodgson's paper.

[69] Forschungsarbeiten, heft. 311, fig. 96.

[70] Messrs. G. M. Clark & Partner, Cairo, Egypt.

[71] See Fig. 8, p. 128, Proc. Inst. C. E., vol. 204.

in South Africa for measuring the output of the compressors supplying this system. The air is thus measured both into and out of the pipe-transmission system, and there is a constant check of the different types of meter. The accuracy of the measurement of compressed air by this means is quite as high as that obtained by the use of any but the very best instruments for the measurement of electric power, and in testing motor-driven compressors it was not unusual for a discrepancy in the electric measurements to be found through the consistency of the air measurements, rather than the reverse.

Besides being used for compressed air, orifices were also at that time in use for metering steam and water flows, such as turbine-condensate discharges, and were thus instrumental in forming the basis of the economical operation of one of the largest power-supply companies. Not only are the meters relatively consistent, but as there is on the mines a large displacement meter for measuring the flow of compressed air, the orifices form a system of absolute measurement also in terms of the fundamental units of volume and weight. The coefficients thus obtained in South Africa were in practical agreement, say to about one-half of 1 per cent, with those given from work done entirely independently in England. The system of measurement has thus the added advantage of being a reproducible one.

To those who have not followed the work step by step during the last twenty years, it may appear from the form of the equations that the method of determining the required coefficients for any particular set of circumstances is of considerable complication. This is due only to the completeness of the paper itself, which deals with the six types of flow that may occur (see beginning of the second page), whereas in practice only one type of flow will be used at the time, and the equations, aided by the appropriate diagrams, are exceedingly convenient.

Although the author has written very fully and given complete references to other papers, these may not always be available, and it is to be hoped that the author will expand this paper at an early date into book form. He will then be able to deal not only with the theoretical part, which is the principal theme of the paper under review, but will also be able to give some of the interesting data upon which his conclusions have been founded. Thus, for example (see the sixth page, top of second column) the author refers to the many experiments that have been made on the flow of very diverse fluids on orifices varied in diameter by 120 to 1. Some of the test methods have been described in Appendix 8, but it might be possible for the author to include some more details of this nature and a short table giving the results for the different fluids employed, more especially perhaps as regards viscous flow, for there has been ample experience during the last twenty years of the measurement of compressed air and of water on a very large scale with great accuracy.

In conclusion it may be of interest that the same plate-orifice method that was started so many years ago is now to be used for the testing of the largest air compressor yet constructed that is now in process of erection in South Africa and that its coefficient has been calculated by the methods of this paper.

Author's Closure

Mr. A. A. Barnes regrets that special formulas to suit the requirements of water engineers and others are not given in the paper. The author considers that in a general paper such as the present one it is undesirable to give special formulas, provided that the formulas which are given are so set out that they can readily be adapted to suit special requirements. It is obvious from Mr. Barnes' contribution to the discussion that he has found no difficulty in deriving from the data given in the paper a special formula that will suit his needs. There is, however, considerable objection to any formula such as Mr. Barnes' Equation [64*b*] in which the numerical constant masks physical quantities which are subject to variation. Thus the constant in his formula masks the value of $(\Omega\phi)$, which will be seen from Fig. 14 to have a value of 0.608 over the larger part of its range, as against the value of 0.602 correctly chosen by Mr. Barnes for his special case. It also masks the value of $W = 62.4$, which only applies for water at the particular temperature of 52 deg. fahr. (See Table 5.)

It is quite as easy and much more satisfactory to work from a general formula such as Equation [5].

Thus, from the data given by Mr. Barnes:

$(\Omega\phi) = 0.602$ (by Fig. 14)

$$N = 2827.44 / \sqrt{\left(\frac{2827.44}{1385.14}\right)^2 - 1}$$

$$= 1590$$

$h = 9.125$

$W = 62.4$ (by Table 5)

Putting these values in Equation [5], we have

$$Q = 0.127 \times 0.602 \times 1590 \times 9.125 \times 62.4$$

(= 2900 lb. per sec.)[72]

Dividing this result by 62.4, the weight of 1 cu. ft. of water at 52 deg. fahr., we have

Discharge = 46.464 cu. ft. per sec.

which is Mr. Barnes' result.

By working from Equation [5], as in the foregoing, all the assumptions as to coefficients and physical constants are clearly set down, and there is no chance of using a formula under conditions where it does not apply.

The test which Mr. Barnes quotes is a very valuable one. It would be almost impossible to obtain greater steadiness of the flow conditions than he had during that test. The author has been in correspondence with him since his contribution to the discussion was sent in and is satisfied that there was no meniscus error in the reading of his manometer and that the volume of the brick-lined reservoir used (which was semicircular in plan and set out with a theodolite) was accurately known to a fraction of 1 per cent. He therefore proposes to take Mr. Barnes' coefficient of 0.5966 for a square-edged orifice of ratio $d_2/d_1 = 0.7$ placed in a smooth 60-in. main as one of the values on which a table of variation of orifice coefficients may be drawn up. (See Table 8.)

TABLE 8 VARIATION OF $(\Omega\phi)$ WITH PIPE DIAMETER

Diameter of pipe in inches	$(\Omega\phi)$
1	0.620
2	0.614
9	0.608
24	0.601
60	0.597

It will be noted that Mr. Barnes' value of $(\Omega\phi)$ is about 0.9 per cent lower than the value given in Fig. 14, which applies to orifices placed in 6-in. to 12-in. internal-diameter cast-iron or steel pipes. This is because the ratio of the central to the mean velocity is greater in the case of the smaller and relatively rougher pipes, a point which is dealt with in the second column of the fourth page of the paper. Other values than those given in Table 8 will, of course, apply to pipes of greater or less specific roughness than that of ordinary commercial cast-iron or steel pipes. The values given in Table 8 are, however, typical of the variation of $(\Omega\phi)$ with pipe diameter. The changes in the value of $(\Omega\phi)$ due to variations in the specific roughness of the pipe in which the orifice is placed are, however, more marked in the

[72] It is not necessary that this step should be worked out.

case of orifices whose diameter ratio is greater than 0.65 and for the segmental orifices whose curve of coefficients is plotted at B in Fig. 14.

In reply to Mr. Ed S. Smith, Jr.: (1) It is interesting to note and to put on record that the method of similarity is now largely used in connection with many other engineering problems than those concerned with airplane, ship, heat-exchanger, pipe-line, and orifice design. It is used in the study of the vibrations of structures,[73] aeroplane wings,[74] rotating shafts,[75] turbine disks,[76] air screws, etc.,[77] in the study of boiler circulations,[78] in examining the effects of pulsations of pressure[79] in exhaust and intake manifolds, in the planning of harbors[80] and the intakes[81] to hydraulic power plants, in charting the distribution of fluid velocities,[82] in investigating the laws of flow through half-drowned sluices[83] and open channels,[84] in the proportioning of centrifugal pumps[85] and surge tanks,[86] in the design of propellers,[87] dynamometers[88] and high-speed vehicles,[89] in the selection of suitable materials for road surfaces[90] and canal beds,[91] in arranging the acoustics[92] and illumination[93] of buildings, and so on.[94]

The first to use the method were probably architects and sculptors when planning temples and large-scale figures. There are many temple and figure models made by the ancient Egyptians in the Museum Boulaq at Cairo.

Froude was the first to apply the method to ship design. A reference to Mr. Clemens Herschel's classical paper of 1887,[95] which introduced the venturi tube for the measurement of water, will clearly show that he expected to obtain similar coefficients for similar venturi tubes of widely differing linear dimensions when these were calibrated with the same fluid, water. The author was the first to apply the method of similarity to geometrically similar venturi tubes, nozzles, and orifices, using different fluids such as water, glycerine, oil, gas, air, and steam; to deduce the viscosity criterion $Q/d_2\mu$ by the same mathematical method which Lord Rayleigh was at the time applying to aeronautical problems, and to examine the upper limits of its application when it was used in connection with compressible fluids, such as air. He was also the first to find the necessity for and to deduce a similarity criterion, when the fluid passing through the orifice or nozzle was appreciably compressed and viscosity effects were negligible. This portion of the work was mainly done in 1909 and 1910 in connection with the large air meters referred to in footnote 5 and in Mr. G. M. Clark's contribution to the discussion.

The values of the coefficients for the orifices given in Fig. 4 only apply to the particular orifice shown in Fig. 5. General coefficients for square orifices with a short length of parallel part are given in Fig. 14.

Mr. Smith's Fig. 25 is useful in indicating the change in coefficient to be expected for a venturi tube or orifice for a given volume discharge through the pipe. It is not, however, so convenient as Fig. 4 when it is necessary to design orifices or venturi tubes for particular flows. In this case d_1 is known and d_2 has to be found.

Both logarithmic and square-root plottings have their special advantages, and both have been used in the paper. The logarithmic plotting has the great disadvantage that it gives a magnified effect at the low values of (ϕ) which are not often used, and cramps the plotting at the high values, where high accuracy is required. This defect is seen in Fig. 25.

The author does not agree that it will be found more convenient to use kinematic viscosity rather than absolute viscosity even in those cases where liquid such as oil is being measured. It is certainly not so convenient to use in those cases where gaseous flows have to be dealt with. The only generally satisfactory way of dealing with gaseous flows is on a weight basis, i.e., to state the flow as so many pounds per second. If the flow is stated on a volume basis, complications with regard to the possible pressure and temperature are immediately introduced. It is quite customary to specify oil flows in gallons per second at a given temperature. This is equivalent to specifying the flow on a weight and not on a volume basis. If, then, the flow is stated on a weight basis, as in most cases it is or should be, the only other factor to be taken into account when calculating the value of the viscosity criterion, besides the linear dimension of the measuring orifice, is the absolute viscosity of the fluid. It therefore does not seem necessary or desirable to introduce the idea of kinematic viscosity in this connection.

Mr. Smith's suggestion that it is more difficult to convert absolute viscosity from one set of units to another than it is to so convert kinematic viscosity does not seem to be true. Kinematic viscosity is absolute viscosity divided by density so that the conversion is actually simpler in the case of absolute viscosity. In any case, the dimensions of each type of viscosity and the necessary conversion factors are given in Appendix 11 of the paper.

In concluding the reply to Mr. Ed S. Smith, Jr., the author desires to add a note of high appreciation of the work which Mr. Smith has done in bringing the method of dynamical similarity, so far as it affects venturi and orifice flows, to the notice of American engineers.

The author feels highly honored that Mr. J. M. Spitzglass should have gone through the paper with such extreme care.

The questions of the roughness of the pipe upstream of the orifice and of the upstream face of the orifice itself, and the importance, when making use of the method of dynamical similarity, of obtaining pipes and orifices of the same relative roughness, has been referred to in various parts of the paper and in footnote 31. The effect of roughness in the pipe upstream of the orifice on the value of the coefficient of discharge has already been dealt with in the reply to Mr. Barnes.

[94] One of the best general discussions of the principles of dynamical similarity and their practical application is given in Glazebrook's Dictionary of Applied Physics, Vol. 1, pp. 81–96.

[95] See Proc. of the Amer. Soc. C. E., Dec. 21, 1887.

Another factor than roughness entered into the tests made by Mr. Spitzglass; namely, that for all sizes of pipe which he tested he used the same length (instead of the same proportional length) of upstream after a right-angled bend. This alone would cause the flow distribution to be different in the case of every orifice tested. When using the $Q/d_2\mu$ criterion it was necessary to ensure that the flow distributions as well as all the geometrical proportions of the orifices compared were similar. It is because variation in the relative roughness is one of the factors which alter the similarity of the flow distribution for the various sizes of pipe worked with that such variation is of importance.

The reason why the author has referred to the first type of flow as dependent upon viscosity only is that his division of the flows through orifices and nozzles into six principal types is based on practical considerations rather than upon hair-splitting theory. Thus, when measuring viscous flows by means of an orifice, the pressure difference required to overcome the viscosity of the fluid as it passes through the orifice is so much greater than the pressure difference required to accelerate it that the latter can be practically neglected. Similarly, when forcing a compressible fluid such as air through an orifice, the compressibility effects can be neglected when the change in the static pressure is small.

The values plotted in Figs. 1 and 1*a* are correct. Their method of calculation is illustrated by the following example:

Thus when $P_2/P_1 = R = 0.70$ and $n = 2$, we read off the curve for $n = 2$ in Fig. 1 that $\phi = 0.775$. This value is calculated from Equation [3] in the following steps:

Putting $R = 0.7$, and $\gamma = 1.408$, we have

$$\begin{aligned} 1/(1 - R) &= 3.33 \\ \gamma/(\gamma - 1) &= 3.45 \\ (\gamma - 1)/\gamma &= 0.29 \\ 2/\gamma &= 1.421 \end{aligned}$$

whence

$$\begin{aligned} R^{(\gamma-1)/\gamma} &= 0.70^{0.29} \\ \text{or} \qquad \log 0.70 &= 1.8451 - 1 \\ &= -(0.1549) \\ 0.29 \log 0.70 &= -(0.1549) \times 0.29 \\ &= -0.0449 \\ &= 0.9551 - 1 \\ &= \log 0.9018 \\ (1 - R^{(\gamma-1)/\gamma}) &= 0.0982 \\ R^{2/\gamma} &= 0.70^{1.421} \\ 1.42 \log 0.70 &= 0.7800 - 1 \\ &= \log 0.6026 \\ (n^2 - R^{2/\gamma}) &= 4 - 0.6026 \\ &= 3.3974 \\ (n^2 - 1) &= 3.0 \end{aligned}$$

whence

$$\begin{aligned} \phi &= \left\{ \frac{3.33 \times 3.45 \times 0.0982 \times 0.6026 \times 3}{3.3974} \right\}^{1/2} \\ &= 0.775 \end{aligned}$$

With reference to points 1–11 in Fig. 3, the points 1–10 were obtained by experiment; point 11 was calculated by Equation [43], using the method described in Appendix 6. Points 1–5 and along the liquid curve were obtained by tests with water and glycerine, as described in Appendix 8, while points 6–10 were obtained by calibration against a standard orifice with high-pressure air with atmospheric pressure at the outlet of the pipe in which the orifice was placed. The test results were then reduced to a common upstream pressure of 1 atmosphere by the method given in Appendix 5.

Some further details of the test methods used are given in the general reply to Mr. Barnes, Mr. Clark, and Mr. Spitzglass.

The author is in disagreement with Mr. Spitzglass that the principal cause of the higher coefficients of large venturi tubes is due to their specific roughness being less. Years ago he thought that this was so, and in order to eliminate the effects of variation in roughness he had perfectly smooth tubes of various sizes made up and tested. The larger tubes still had the larger coefficients at the flows worked with. It was only when he had determined a sufficient length of the Ω vs. $Q/d_2\mu$ curve for one tube to appreciate that the shape of the venturi discharge curve for any one tube tested over a sufficiently large range was generally as shown by the curves in Figs. 4, 10, and 11, and had noticed that the larger tubes worked at higher values of $Q/d_2\mu$ that the true explanation became apparent.

Mr. Spitzglass points out that the orifice, unlike the venturi tube, is practically frictionless. Though, as stated in footnote 31, the coefficient and discharge can be slightly increased by making the upstream face of the orifice rough, there is no difficulty in making this face of sufficient smoothness to avoid any appreciable increase in the coefficient due to roughness of the plate. This frictionlessness of the orifice, with its streamlines which are constrained only at the square edge, which is so easily made to specification and inspected, makes it more satisfactory than any form of nozzle can be as a secondary standard of flow measurement. Fig. 14 shows that if the value of d_2/d_1 for a square-edged orifice with a very short length of parallel part is kept below 0.65, the value of the coefficient of discharge may be taken as 0.608. Theory shows that if the convergence of the streamlines of a "perfect fluid" is taken into account, the term $\pi/(\pi + 2)$ should be introduced into Equation [1] for such orifices and for sharp-edged orifices. As the numerical value of $\pi/(\pi + 2)$ is 0.611, this means that if the discharge equation had been based on the full theory of the orifice instead of upon a modified nozzle theory, the coefficient of discharge of orifices for which d_2/d_1 is less than 0.65 would have been $0.608/0.611 = 0.996$, or only 0.4 per cent different from theory.

Mr. Spitzglass has given only part of the reason for the rise in the coefficient of orifices as the $Q/d_2\mu$ value is decreased. The increasing effect of viscosity suppresses the effects of momentum, and so reduces the convergence of the streamlines passing through the orifice. The vena contracta, and in consequence the coefficients of discharge, are thus both increased. The author has tests which show that this effect occurs even when the orifice ratio is ten times less than the lowest value, 0.421, given in Fig. 4. He first called attention to the variation of the coefficient of contraction with viscosity during the discussion of a paper at the Institution of Civil Engineers in 1921.[96]

Mr. Spitzglass' Fig. 26 is interesting. If an attempt is made to separate out Ω and ϕ, the value of ϕ should, of course, be calculated from the assumed value of the diameter of the vena contracta and not from the diameter of the orifice. But as it is impossible to calculate the diameter of the vena contracta for an orifice without making assumptions as to the effects of compressibility and turbulence, it has seemed to the author best not to endeavor to effect any such separation for orifices, but to treat $(\Omega\phi)$ as one variable, though in the past he has made many attempts on the lines of Mr. Spitzglass's Fig. 26.

The P_2/P_1 vs. ϕ curves for air and steam which he and his assistants prepared in 1909–10 have been included in the paper only because of their value in calculating out the discharge through nozzles, for which Ω usually lies between 0.94 and 0.99.

With regard to the tests given in Fig. 6, the piping used was smooth-drawn brass tubing for 20 diameters upstream and 10

[96] See the author's contribution to the discussion of MacDonald and Hurst on "The Measurement of the Discharge of the Nile Through the Sluices of the Assuan Dam," Proc. Inst. of Civil Eng., vol. 212, 1921, part 2.

diameters downstream of the orifice, selected commercial wrought-iron tubing being used upstream and downstream of this. All except the round-dotted portions of Fig. 6 were obtained by extrapolation, using the method given in Appendix 6. The actual experimental points in Fig. 6 are shown marked by circles or crosses.

In reply to Mr. Sprenkel, the coefficients for self-contained orifices with the steadying cone are not the same as for an orifice in a straight pipe except when the hole is very small, when the coefficient is about 0.61. The coefficients for orifices used with the steadying cone shown in Fig. 8, as well as being different from the coefficients given in Figs. 4 and 14, also vary with each size of main, as the cones are of equal length, but of different diameters, so that geometrical similarity is not preserved.

The reason why the curve *A* in Fig. 14 differs from the other curve in Fig. 7 is that the orifice shown in Fig. 5 had a relatively long parallel portion, was made of fairly thick material, and was of constant width for all ratios of d_2/d_1. The orifices whose coefficients are given in Fig. 14 had, on the other hand, a very thin parallel portion so that they might almost be considered sharp-edged, and the thickness of the plate increased as the diameter of the pipe increased, instead of remaining constant. Further, as the curve given in Fig. 14 was intended for general use, and aimed at being accurate only to within plus or minus 1 per cent, any small deviations from exact straightness were faired out before drawing it up.

The author can find no reference in Appendix 10 of any suggestion to throttle the meter pressure pipes. A reference is made to this possibility on the seventh page, second column, but it is stated there that the "method is not practicable unless the pressure pipes are kept free from dirt or condensation of moisture."

In the discussion of Messrs. Judd and Pheley's paper in 1922,[97] the author stated that the pressure change should be considered as a symptom rather than as a cause. He has now (1929) nothing to add to that statement.

[97] Proc. Amer. Soc. Mech. Eng., Dec., 1922.

It is stated on the seventh page of the paper, and again in Appendix 10, that a number of assumptions have had to be made in order to derive the CFL/ZQ criterion. If the criterion is used bearing these clearly in mind, it will be found to be an extremely valuable guide to a mass of otherwise almost wholly uncoordinated experimental facts. During the past eight years the author has applied this criterion to many hundreds of cases of pulsating flows, and always with complete success. Mr. Sprenkel is, of course, correct in suggesting that a capacity which causes eddies or otherwise retards the flow produces a greater damping effect than one which does not do so. The CFL/ZQ criterion takes this effect into account to a considerable extent because eddies or vortices produced in the chamber providing the capacity C cause an increase in the value of the loss of pressure L.

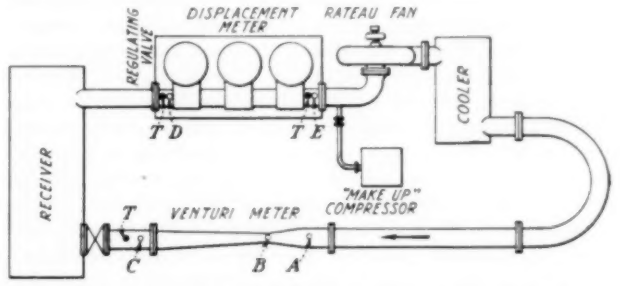

FIG. 30 ARRANGEMENT OF RAND AIR-METER CALIBRATION PLANT
(The pressure of the air was taken by a sensitive pressure gage at *A*; differential pressures were taken between *A* and *B*, *A* and *C*, *A* and *D*; *D* and *E*; temperatures were taken at the points marked *T*.)

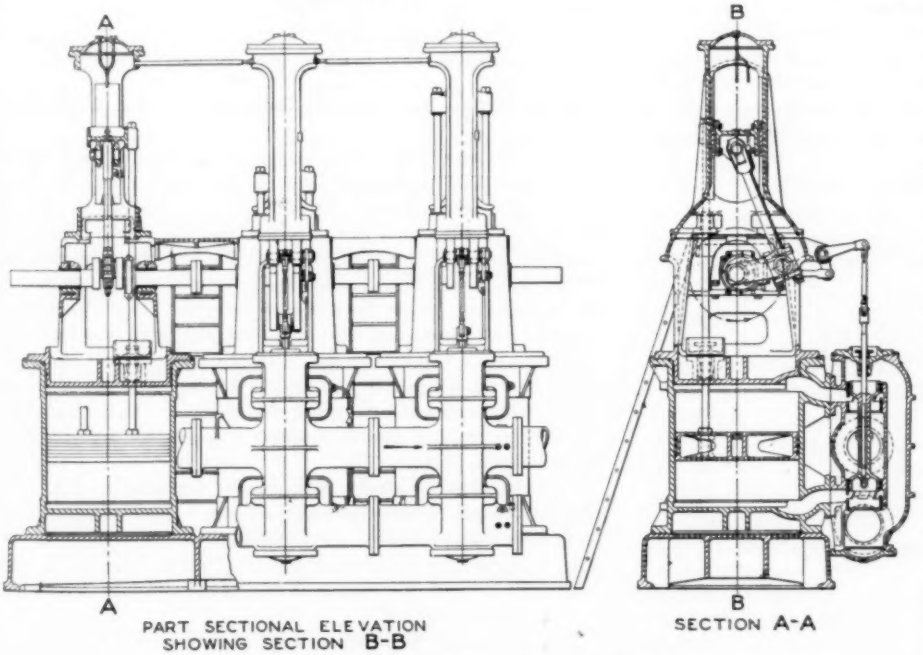

FIG. 29 THE RAND DISPLACEMENT METER

Mr. Barnes, Mr. Clark, and Mr. Spitzglass ask that further details shall be given as to test methods used. In this connection the following notes may be of interest:

The meters referred to in footnote 5 and also the first large orifices made were calibrated on a plant which was designed and erected specially for the work. The following illustrations and description are taken from the author's paper to the Institution of Civil Engineers in 1927:[98]

"The meters required in connection with the Victoria Falls and Transvaal power scheme, together with various sizes of venturi tubes, nozzles, and orifices, were calibrated in a special plant, which was designed and built at Erith by Messrs. Fraser and Chalmers, in consultation with Mr. A. M. Robeson, Mr. A. Smart, and the author. The plant was erected in the first instance to the author's specification in 1909, and, after being placed at the disposal of Messrs. Kent for about six months by Messrs. H. Eckstein and Company at Erith, was taken down and re-erected at Ferreira Deep on the Witwatersrand. It is now the standard air-calibration plant for South Africa.

"The air to be measured is passed through a large displacement meter [Fig. 29] which is built somewhat on the lines of a

[98] Proc. Inst. C. E., vol. 204, pp. 108–193.

steam engine. It has three cylinders 36 in. in diameter, and the stroke is 27 in. The admission and discharge of the air to the cylinders are controlled by means of piston valves which are set to cut off exactly at the top and bottom of the stroke. The stroke volume is 95.156 cu. ft., and the meter therefore passes 50 lb. weight of air per revolution at 100 lb. per sq. in. (abs.) and 513 deg. fahr. (abs.); or roughly, 1 ton per minute at the maximum speed at which it is designed to run. This displacement meter forms part of a closed air circuit [Fig. 30] wherein the air is circulated by a single-stage Rateau fan, which is driven by a 50-hp. motor at 2500 r.p.m., and produces a difference of pressure of about 2.5 lb. per sq. in. when the air is at a pressure of 100 lb. per sq. in. The pressure in the circuit is maintained by a small 'make-up' compressor, requiring about 30 hp., which delivers into the circuit between the displacement meter and the Rateau fan. After leaving the fan the air passes through a cooler, so that the temperature in the remainder of the circuit may be kept constant. It is then passed successively through the meter to be tested and the displacement meter."

The pressure of the air was taken by a sensitive pressure gage at *A*. Differential pressures were taken between *A* and *B*, *A* and *C*, *A* and *D*, and *D* and *E*. Temperatures were taken at the points marked *T*.

With this plant it was possible to obtain very accurate measurement of the air, as there was no leakage at all from the displacement meter, and there was practically no leakage across it owing to the small difference of pressure required to operate it. The slight pulsations which occurred when the displacement meter was running at its maximum speed were damped out by means of the receiver and regulating valve shown.

The cost of this plant at pre-war prices was about £4000.

Another plant on which very valuable tests were taken in 1913 was the test plant at Ragged Chutes in Northern Ontario, which was placed at the author's disposal for several weeks by the courtesy of the Northern Ontario Light and Power Company.

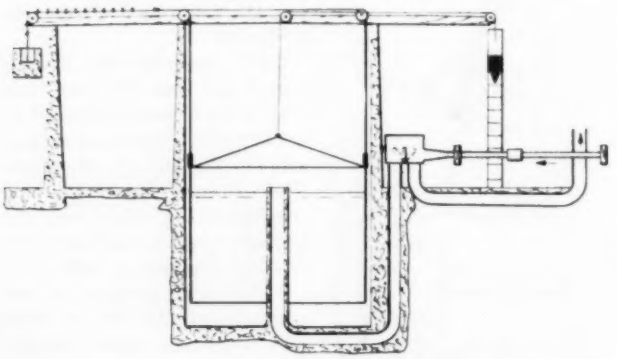

FIG. 31 TEST HOLDER AT RAGGED CHUTES

This plant is illustrated in Fig. 31. It consisted of a gas holder of 250 sq. ft. cross-section and 3000 cu. ft. capacity. The air passing through the orifice to be tested was held at the desired pressure by means of the two valves shown, and was discharged into the gas holder at practically atmospheric pressure. A throw-over valve with a deep water seal enabled the air passing through the orifice to be discharged into the gas holder or to atmosphere as desired. In its middle position it enabled the gas holder to discharge to atmosphere, the high-pressure air supply being of course, cut off. Compensation for the change in buoyancy of the gas holder due to immersion was made by means of weights attached to the cord carrying the compensating weight.

The movement of the gas holder was indicated on a steel tape marked in tenths and hundredths of a foot, a weighted pointer being attached by a metal cord to the center of the gas holder. It was easily possible to read the position of this pointer to an accuracy of one cubic foot.

The gas holder was housed in a special heat-proof building having windows only on its northern side. This arrangement eliminated changes of temperature due to the varying intensity of the sun's rays, which is a very frequent source of inaccuracy in the measurement of gaseous quantities by means of gas holders.

The source of air was a Taylor hydraulic compressor which delivered air that was perfectly dry and free from the slightest pulsation. Several thousands of horsepower were available from the compressor, which utilized the whole discharge of the

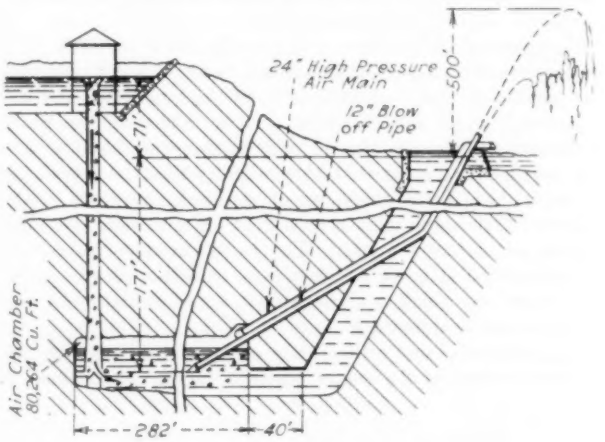

FIG. 32 TAYLOR HYDRAULIC AIR COMPRESSOR

Montreal River. Fig. 32 shows the main features of this compressor.

It will be seen that a dam was built across the river above the original fall at Ragged Chutes and that a vertical shaft some 242 ft. deep was sunk into the rock. A horizontal passage 322 ft. in length which had a raised roof for 282 ft. led from this vertical shaft to a rising shaft at the lower side of the fall. These shafts and their connecting passages were of sufficient size to take the whole discharge of the river. Air was sucked down by the river in its fall, and then separated out from the water at about 110 lb. per sq. in. in the underground chamber, which had an air capacity of 80,264 cu. ft. A relief pipe was provided through which excess air could escape. Various governing and controlling devices ensured a supply of high-pressure air at uniform pressure.[99]

On this plant extremely careful tests were taken with thin-plate orifices of various diameter ratios in a piece of bored 6-in. main which was specially taken to Ragged Chutes for the purpose. The orifices both before and after the air calibration were calibrated by means of water at the Messrs. Kents' hydraulic-test plant at Luton.

This hydraulic-test plant consists of a large tank in the floor of the test shop, a centrifugal pump delivering water to a large tank placed in a water tower, and a down-pipe passing from this tank to the meter to be tested, which meter discharges through a control valve into the tank in the floor of the test shop. The plant is so arranged that the quantity of water passed can be measured either in the large tank in the water tower or in smaller tanks before it is passed into the tank in the floor of the test

[99] It would seem highly desirable that such a plant as that which existed at Ragged Chutes in 1913 should be acquired for test purposes by those interested in the accurate measurement of gaseous fluids.

shop. The plant is capable of measuring flows up to 100,000 gal. an hour. The various tanks used were originally calibrated and are periodically checked by means of weight measurements.

The author has also made tests on orifices and venturi tubes against drum-type gas meters of sizes varying from one-tenth of 1 cu. ft. per revolution to 750,000 cu. ft. per hour. Such meters are calibrated against small, temperature-shielded gas holders, and will measure accurately to within plus or minus 1 per cent under test conditions.

A number of check tests on orifices have been taken from time to time for the satisfaction of clients. The first square-edged orifice which the author installed in South Africa in 1911 was checked for the satisfaction of his clients against a venturi tube which had been previously calibrated against the displacement meter shown in Fig. 29. In this test the orifice was put in series with the venturi tube with a sufficient length of piping in between them. Air at 100 lb. pressure was then passed through both, and simultaneous readings were taken over a period of time. Later on, for the satisfaction of another client, twelve orifices identical with the one referred to were placed in parallel with sufficient lengths of piping upstream and downstream of them, and the combined discharge at 100 lb. pressure was then passed through an orifice placed in a 44-in. main. Simultaneous readings were taken on twelve manometers connected across the twelve 12-in. orifices in parallel and upon a manometer connected across the orifice in the 44-in. main.

The cost of this set of tests worked out at about £50 an hour.

In the test results plotted in Fig. 6, which show the values of $\alpha\phi$ for discharges through orifices at high-pressure ratios, the air was measured by passing it through calibrated orifices working at high static pressure, but at low-pressure differences, and placed in mains much larger in diameter than the main in which the orifice itself was placed. These calibrated orifices were fed with air from a large receiver, which in turn was supplied by an air compressor. The ends of the pipes which contained the test orifice were open to atmosphere.

In addition to the tests enumerated, the author has made a large number of tests on the flow of steam at various degrees of wetness and superheat through orifices by condensing the steam and weighing it. Such condensate tests have been taken on mains up to 12 in. in diameter. He has also tested very small orifices for gaseous discharge by discharging gases such as oxygen and chlorine through them from steel bottles containing the compressed gas, the bottles being placed on a weigh bridge and flexibly connected to a pipe containing the orifice.

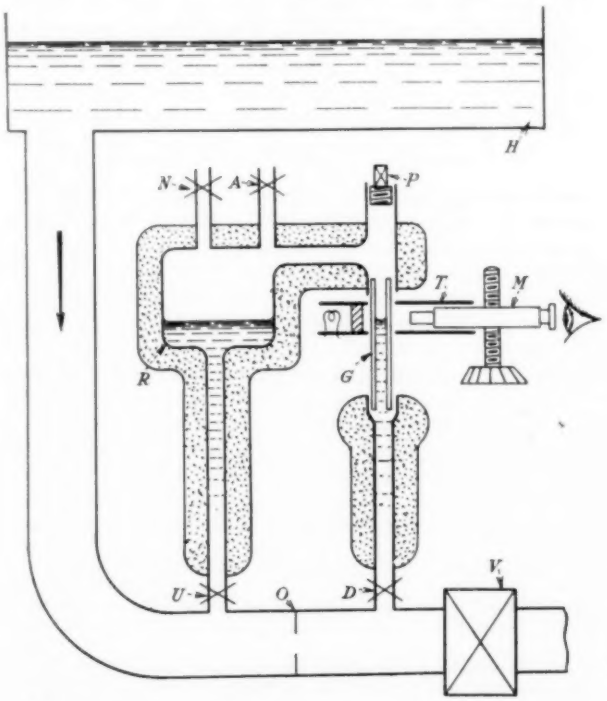

FIG. 33 DIAGRAM OF MICROMANOMETER FOR LIQUID FLOWS

Mr. Johansen's contribution is interesting in showing by its agreement with the author's results obtained by the use of viscous fluids that extremely small differences of water pressure can be measured with accuracy. Since the paper was written, the author and one of his assistants (Mr. H. E. Dall) have again attacked the problem of measuring very small heads of water with accuracy, and have found it possible, with the apparatus shown diagrammatically in Fig. 33, to read accurately down to $^1/_{5000}$th of a centimeter.

The apparatus consists of an inverted single-tube manometer containing a reservoir R and a gage glass G. This manometer is connected across the orifice to be tested, O. The pressure pipes are brought off at the side of the main and not at the top, as shown in the diagram, in order to avoid air bubbles rising into the manometer. Liquid is supplied from an overhead tank H, and the flow is controlled by a valve V placed on the downstream side of the orifice. The valves U and D control the flow of liquid into the manometer, and a plug P makes the interior of the gage glass accessible. Before a series of tests are taken the gage glass is carefully cleaned with hydrochloric acid or other suitable chemical. Air is pumped in with a bicycle pump through the valve A, and the valves U and D are then opened. Any excess air is allowed to escape through the needle valve N until the meniscus in the gage tube G comes to the desired reading on the micromanometer M.

When the flow is turned on, the level of the meniscus in the gage tube G falls, while that in the reservoir R rises slightly, the amount of rise being easily calculated when the ratio of the area of the reservoir to the area of the gage glass is known, and it is remembered that the volume of air trapped at the top of the reservoir remains constant so long as the static pressure on the orifice and the temperature of this air remain constant. The static pressure is maintained constant by having the supply tank H of large area so that the fall of level during a test is an imperceptible fraction of the total static head and by ensuring that the surface of the water in the supply tank and the tank itself are free from disturbance and vibration. Thus, if the tank is in a tower in a windy situation it will be found impossible to take accurate tests on a windy day owing to the variation in static pressure caused by slight waves set up in the tank due to the rocking of the tower.

The internal diameter of the gage-glass tube is approximately 0.3 in., the magnification of the microscope 40 diameters, and the micrometer screw $^1/_2$ millimeter pitch. The meniscus is shielded from extraneous light by a tube T through which the gage glass passes and which slides on the object glass of the microscope. The meniscus is illuminated by a lamp which is attached to this shield. This ensures that the particular portion of the meniscus on which the microscope reading is taken does not change its position through variations in the relative position of the source of illumination. (Actually the lamp is placed about 6 in. away from the meniscus and not close up, as shown, in order to prevent error due to heating the meniscus. The light is further passed through a glass plate before reaching the gage tube in order that the heat rays may be absorbed.)

The air in the reservoir is shielded from temperature changes, as any variation in the temperature of this air will cause its expansion or contraction, with consequent movement of the

meniscus. In order to ensure that no such contraction or expansion has taken place a zero reading is taken before and after each test. The pressure pipes leading from the orifice are also shielded from temperature changes in order that the density of the liquid in these pipes shall not alter and so affect the reading. In order to avoid error due to any difference of density of the liquid in the pressure pipes, these are made short and laid with a very slight slope so that the meniscus is practically at the same level as the center line of the orifice.

With this apparatus it is possible to read accurately down to $^1/_{5000}$th of a centimeter of water and to estimate the reading to $^1/_{10,000}$th of a centimeter.

The foregoing notes also cover a point raised by Mr. Connet.

The author is indebted to Mr. Johansen for his careful repetition of the tests on which Fig. 9 of the paper was based. The results given in Fig. 9 were taken with a 6-in. orifice in a rough cast-iron pipe about 1909 in the early days of orifice work, while those by Mr. Johansen were taken in a smooth brass pipe in 1929 after 20 years' improvement in technique. These facts may explain the slight difference between the results. At the same time it should be noted that the pressure distribution curves vary with the value of $Q/d_2\mu$, so that a complete statement of what happens cannot be made on a single set of curves which apply only over a limited range of $Q/d_2\mu$ values.

Mr. Johansen's question as to the effect of roughness of the pipe upstream of the orifice has already been answered in replying to Mr. Barnes.

Mr. G. M. Clark's contribution to the discussion is of special interest as he was responsible for the drafting of that part of the Victoria Falls & Transvaal Power Company's contract which dealt with the basis on which the compressed air was to be measured and sold. This contract provided for the measurement of the air on an energy basis so that the readings of the air meters could be directly comparable with the readings of the electricity meters and the whole of the heat balances of the plant could be drawn up on an energy basis. The coal, for instance, was rated at so many kilowatts, instead of at so many B.t.u. per pound. The "air unit," in terms of which the meter had to register, was defined as the "quantity of air which would be compressed from the mean atmosphere and temperature on the Rand (12.086 lb. per sq. in. abs. and 60 deg. fahr.) to the pressure of delivery by the expenditure of one kilowatt-hour of energy in an isothermal compression process of an agreed overall efficiency." This "air unit" is also defined by the equation given in footnote 5.[100] Mr. Clark was also responsible for the acceptance of the first large compressed air meters which the author designed some twenty years ago, and which are referred to in footnote 5. In these days when research workers all over the world are intensively studying the orifice as a method of measurement it is gratifying to have testimony as to the high accuracy of the work done twenty years ago when every step made was a step in the dark and involved risk of failure. The large displacement meter referred to by Mr. Clark is shown in Fig. 29.

In concluding his reply to the discussion, the author desires to make reference to Mr. Clemens Herschel, whose classical work on the venturi tube first made the accurate measurement of fluids in closed conduits possible.

FSP-51-43

Low-Temperature Carbonization of Southern Appalachian Coal

By LEO HOLDREDGE,[1] KNOXVILLE, TENN.

After discussing the principal reasons for the low-temperature carbonization of bituminous coal, the author describes briefly the four types of methods used or proposed for low-temperature carbonization, and then gives details regarding a laboratory experiment carried out at the University of Tennessee Engineering Experiment Station, the primary purpose of which was to produce a smokeless fuel in a form suitable for domestic use. A summary of the results of ten tests of a high-volatile northern Tennessee steam coal is included which gives quantities of semi-coke, gas, tar, and tar products produced, together with their gravities, heating values, etc. The coke obtained is easily ignited, burns smokelessly even in an open grate, and, the author believes, should find a market as a domestic fuel.

A CENTURY ago Sir Robert Peel said that the future belonged to the nation which could produce the most coal. In 1910 a German writer remarked, "The future belongs to the nation which makes the best uses of its coal resources." Both of these expressions are overstatements if they are taken at their face value. Many other elements besides its supply and use of coal enter into the civilization of any nation. If other things are equal, the future will belong to the nation which possesses and efficiently uses an abundant coal supply.

Low-temperature carbonization of bituminous coal is one of the proposed methods for making efficient use of our coal resources. The fuel resources, the practice most commonly followed in the use of fuel, the economic conditions, and the demand for a raw material for making synthetic chemicals, will determine when low-temperature carbonization is an efficient method of using our coal supplies.

There are three principal reasons for the low-temperature carbonization of bituminous coal:

1 Production of a free-burning smokeless fuel
2 Recovery of the by-products
3 Increase of the value of coal as mined.

Production of Free-Burning Smokeless Fuel

The value of a smokeless fuel can best be appreciated by observing the damage done by smoke. Definite data on the damage from smoke cannot be compiled, but it certainly is enormous. Estimates of from $500,000,000 to $550,000,000 annual loss in the United States have been made by investigators who used surveys of the United States Government as the bases for their calculation. This damage may be considered under four divisions: (*a*) Damage to vegetation, (*b*) damage to structures, (*c*) damage to health, and (*d*) economic damage.

Carbon dioxide from the air is assimilated by the plant by means of the stomatal openings in the leaves. Oxygen is eliminated. As the animal inhales the oxygen and exhales carbon dioxide, so the plant takes in carbon dioxide and gives off oxygen. Sunlight is necessary for this life process of the plant.

Soot, the solid matter of smoke, consists principally of free carbon, tarry matter, and ash. The soot clings so tenaciously to anything with which it comes in contact that it is not even removed by hard rains. It is deposited on the leaves of the plant and interferes with the vital interchange of carbon dioxide and oxygen. If the leaves were covered with the tarry matter until the openings were completely closed, the plant would die. The partial closing of these openings interferes with the vital processes of the plant so that growth is retarded.

It is also known that sunlight is necessary for plant growth. Smoke greatly reduces the intensity of the sunlight and consequently retards the plant growth.

In normal country air there are four parts of carbon dioxide to ten thousand parts of air. This carbon dioxide ratio is increased in the areas where smoke is produced. This factor itself would increase plant growth, but it is more than counterbalanced by the tarry deposits on the leaves and the decreased intensity of sunlight due to the smoke. But if the coal were burned without smoke, the carbon dioxide ratio would be increased still more and the tarry deposits would be absent. This would stimulate plant growth.

The damage that smoke causes to buildings is twofold. The acids in the smoke react with the materials out of which the building is constructed. In course of time this damages the building in usefulness and appearance. The smoke also mars the beauty of the building by reducing all parts of it to a dull drab color. Light shades and pleasing contrasts in color with which the architect has beautified the building are covered with grime and soot.

But the greatest damage done by smoke is the damage to health. The following extract from the report of the Anti-Smoke Committee of the St. Louis Medical Society indicates the extent of this damage.

> The permanent deposits of carbon in the lungs and the thickening of the air passages must reduce the normal lung capacity. This in turn definitely lowers the general vitality and resistance to disease. Chronic diseases of the nasal sinuses, throat, and deeper air passages of the lungs are aggravated, prolonged, and often rendered incurable. Ordinary colds occur more frequently and tend to progress into more serious conditions. The failure of proper interchange of gases in the lungs also causes mental sluggishness and depression. These definite effects upon our bodies and minds, in addition to the economic losses to the community through the necessity of constant cleansing of every article in our households, offices, and business places seem to us to warrant a united and determined effort to find a solution of the smoke problem. We must rid ourselves of our worst personal and civic nuisance. Many persons leave our city or fail to come here on account of smoke.

Not only is there damage to vegetation, buildings, and health by smoke, but there are also large economic losses. The amount of carbon in the smoke which gives it the black color may not be large. The amount of invisible hydrocarbons which are present in the smoke often represent a loss which is several times as large as the loss in the visible smoke. Smoke is evidence of incomplete combustion. Lack of smoke is a strong indication of complete combustion.

The decreased heat conductivity due to deposits of soot represent a large loss. Carbon in any form is a good non-conductor of heat. In the loose, fluffy form of soot it is one of the best-known non-conductors. Sooty heating surfaces are found with

[1] Instructor in Mechanical Engineering, University of Tennessee. Assoc-Mem. A.S.M.E.

Presented at the Knoxville Meeting, Knoxville, Tenn., March 21-23, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

smoke. Clean heating surfaces are the rule where no smoke is produced.

The constant cleaning of draperies, clothes, and indeed every article about the home, office, and business house, causes a large loss. Not only is there the cost of the cleaning, which is large, but there is also the larger loss due to decreased length of usefulness of the articles themselves. This loss caused by smoke is certainly of no small size.

In most cities the total amount of smoke made by the domestic users of coal is larger than that made by either the railroads or the industries. Smokeless cities will be a dream and a vision until the household user is furnished a fuel which he can and will burn smokelessly. That is where low-temperature carbonization of coal should help. It provides a smokeless fuel which is free burning and can be used in the ordinary household appliances.

Recovery of By-Products

The second reason for low-temperature carbonization of bituminous coal is for the recovery of the by-products. In opening the International Conference on Bituminous Coal held in Pittsburgh, November 15–18, 1926, President Baker of Carnegie Institute of Technology said:

> In less than a generation the present method of shipping coal to be burned in its raw state under boilers hundreds of miles from the mines will appear to have been primitive and rudely unscientific. Just what form the developments of fuel technology are going to take one may not forecast. Of one thing we are certain, and that is that the changes will be radical, and it may not be too much to hope that this present International Conference on Bituminous Coal may mark a turning point, at least in this country, in the science of the utilization of coal.

The development of the internal-combustion engine in the last few decades has caused a very large demand for low-boiling motor spirits. The principal source of this fuel at present is petroleum. In 1924 the petroleum refineries in the United States produced 8,960,000,000 gallons of gasoline. Gasoline from natural gas amounted to 934,000,000 gallons. The quantity of motor benzol produced from coal in the same year is not known exactly, but 100,000,000 gallons is perhaps about right. The petroleum refineries produced 2.26 times as much gasoline in 1924 as they did in 1919.

The world's known supply of petroleum will not last many decades at the present rate of production. It is reasonably certain that other deposits of petroleum will be discovered and that better methods of recovery will increase the production from the present fields. But in spite of this, there is a shortage of oil in some parts of the world at present. Just when this shortage might become acute enough to interfere seriously with the industry and commerce of any nation would be difficult to forecast.

Table 1, from "The Conversion of Coal into Oil," by Fischer (English translation by Lessing), shows the coal resources of the world.

TABLE 1 COAL RESOURCES OF THE WORLD

Continent	Total deposits, including proved, probable and possible, million tons	Proved deposits, million tons
Europe	784,190	274,189
North America	5,073,431	414,804
South America	32,097	2,087
Asia	1,279,586	20,502
Australia	170,410	4,073
Africa	57,839	500

Coal is being produced at a rate of 1,250,000,000 tons per year. From Table 1 it may be seen that the world's supply of coal will last for thousands of years at the present rate of production. On a heat basis the annual production of oil amounts to about 14 per cent of the coal production. Or in other words, an increase of 14 per cent in the amount of coal mined would equal all the oil produced as far as heat is concerned.

Low-temperature carbonization of bituminous coal can supply some of the world's need for a low-boiling motor fuel, and thus supplement a limited petroleum resource with a fuel from an almost unlimited coal supply.

The by-products of low-temperature carbonization may become of greater use in the fields of chemistry than in the fuel field. Coal tar is a raw material for a very large number of organic chemicals. With the increase in the number and importance of the synthetic organic compounds, the amount of coal tar used in the chemical industries is sure to become greater.

Increase of the Value of Coal as Mined

The free-burning smokeless fuel is of greater value and commands a higher price than a coal which produces smoke when burned under the conditions which obtain in domestic heating. This is best seen by a comparison of the prices on anthracite, low-volatile bituminous, and high-volatile bituminous coals. On September 1, 1927, the prices at Minneapolis, Minnesota, were as follows:

Anthracite		Pocahontas		Kentucky	
Egg	$13.20	Block	$8.00	Block	$6.00 to $7.00
Stove	13.60	Mine run	5.75	Mine run	5.75
Nut	13.20	Screenings	4.75	Screenings	4.75
Pea	11.05				

All prices f.o.b. Duluth, Minnesota.

These prices are quoted from *The Black Diamond*, September 3, 1927, issue.

In the same issue of that journal the spot prices at eastern Kentucky mines were given as follows:

Block	$2.50 to $3.25
Lump	$2.00 to $2.50
Egg	$2.00 to $2.50
Nut	$2.00 to $2.25
Mine run	$1.50 to $1.75
Screenings	$1.10 to $1.35

Low-temperature carbonization of bituminous coal should become of practical economic value if it can take low-priced mine run, or nut and screenings from bituminous coal mines and convert that raw material into a clean, free-burning, smokeless semi-coke which will replace the anthracite coal which is becoming quite scarce.

Methods of Low-Temperature Carbonization

The methods used or proposed for low-temperature carbonization may be divided into four general types, depending upon the type of retort used and the method of applying heat.

1 Externally heated retorts in which the coal is in thin layers and is not stirred during carbonization
2 Externally heated retorts in which the coal is stirred during carbonization
3 Internally heated retorts with the coal filling the retort and the heat supplied by means of hot gases or superheated steam
4 Internally heated retorts with the coal pulverized and heated in suspension by means of hot gases.

The method which is best to use in any given case will depend upon the coal which is to be used and the products which are to be made.

If a coking coal is to be used and a lump semi-coke is desired, the externally heated retort, in which the coal is quiescent during carbonization, may be used. The great difficulty in this

type of retort is in transferring the heat to the coal at the low temperature gradient which is necessary. Coal is a very poor conductor of heat. This necessitates the use of thin layers of coal. As a result the output is low and the investment is large for the yearly output.

With coal of from 32 to 35 per cent volatile matter, such as is common in the Southern Appalachian coal field, a gas yield of from 2500 to 4000 cu. ft. per ton may be expected. This gas should have a heat value of about 1000 B.t.u. per cu. ft. The tar yield would be above 30 gal. per ton. (Laboratory yields much higher than this have been secured.)

The externally heated retort in which the coal is stirred during carbonization seems suited for carbonizing non-coking coals. This method should result in faster heating than where the coal is not stirred. The semi-coke would be in a pulverized form, and briquetting would be necessary if a domestic fuel were to be produced.

A coking coal is too sticky and gummy when heated to use in a retort of this type unless special devices are used to prevent the coal from sticking to the sides of the retort. The K.S.G. system has apparently overcome this difficulty by use of two concentric cylinders. The cylinders are slightly inclined. The raw coal enters the lower end of the inner cylinder and by means of vanes on the inside of the cylinder is carried to the upper end of the cylinder as it slowly rotates. In the inner cylinder the coal is warmed, but the real carbonization occurs as the coal descends the outer cylinder. A suitable lump semi-coke is said to be made by this process.

The internally heated retort with the coal filling the retort and the heat supplied by hot gases or superheated steam would seem to have some advantages. As was previously mentioned, coal is a very poor conductor of heat. The hot gas or steam could carry the heat to every part of the mass. Certain difficulties have arisen with the use of these retorts. If the heat is carried to the charge by means of flue gas there is a very large yield of a gas low in heat value. If superheated steam is used the tar will be very intimately mixed with several times its own weight of water. The tar is not easily separated from this water.

The Turner process, which is an outgrowth of the process for distilling Scottish oil shale, uses superheated steam. The process has one unique feature. A series of valves are operated so that the steam builds up a pressure of a few pounds above atmospheric pressure. Then the admission valve is suddenly closed and the exhaust valve at the same time opens wide, so that the pressure at once falls. This process is then repeated every few seconds. By this process the inventor claims that no non-condensible gases are produced, and that a satisfactory semi-coke is made.

The McEwen-Runge system carbonizes the pulverized coal with hot gas as it falls through a vertical retort. The coking properties of the coal are destroyed in a preheating process so that the semi-coke is left in a pulverized form. It is used as a powdered fuel for boilers, and is said to be better than raw coal for this purpose.

This outline of the methods of low-temperature carbonization is intentionally very brief. For more complete information reference is made to numerous articles in the technical press and to the recent books on the subject.

LABORATORY EXPERIMENT AT THE UNIVERSITY OF TENNESSEE ENGINEERING EXPERIMENT STATION

The primary purpose of the experiment was to produce a smokeless fuel which would be in a form suitable for domestic use. In addition to this there was a desire to determine the coking characteristics of representative Tennessee coals, when coking at low temperatures; it was also desired to learn enough about the tar produced so that its most profitable use could be predicted.

Preliminary Tests

Some preliminary tests were made in order to determine, if possible, the amount of volatile matter which could be left in the coal, and at the same time have a smokeless fuel. Five 5-gram samples of coal in crucibles were heated in a muffle furnace. The coal used for these tests had 34.57 per cent volatile matter. Four tests of this kind were made. The amount of volatile matter left in the samples was as follows: 12.49 per cent, 15.09 per cent, 16.74 per cent, and 20.34 per cent. Each sample was then pulverized and burned in a crucible. The samples with 12.49 per cent and 15.09 per cent of volatile matter showed no smoke whatever. Smoke was barely perceptible on burning the sample with 16.74 per cent volatile matter. The sample with 20.34 per cent volatile matter was quite decidedly smoky on burning. It should be noted that the amount of volatile matter as given above is the percentage of the original sample. The amount of volatile matter in the semi-coke itself of these same samples is 14.28 per cent, 17.77 per cent, 20.11 per cent, and 25.53 per cent. From these tests it is concluded that the volatile content of the coal used for these tests must be reduced to 18 or 20 per cent before the coal will burn in the crucible without smoke.

Another series of tests was made with a mixture of hard foundry coke and raw coal. Each was pulverized and then the mixtures were burned in the crucible. This mixture would not burn in the crucible without smoke whenever the amount of volatile matter in the mixture was over 3 per cent. From these two series of tests it is concluded that it is not so much the amount of volatile matter in the coal as its form which causes the smoke.

Coal Used

Eight of the coals tested were from the northern Tennessee Coal field. One gas coal from southern Kentucky was tested. A few tests were run on each of these coals, and then a series of tests were made on one coal which had the following analysis:

Ash	6.56 per cent
Moisture	1.68 per cent
Volatile matter	35.71 per cent
Fixed carbon	56.65 per cent
Heating value	13,916 B.t.u. per lb.

This coal was taken from the thickest seam in the state. The coal is at present sold entirely as a steam coal. It is quite strongly coking, but it is too high in sulphur to be used for making metallurgical coke.

All the coals used were high-volatile coals, since this kind of coal predominates in the Southern Appalachian field.

Apparatus Used

The first apparatus used was designed so that the coal was heated by superheated steam. The first part of this apparatus was a superheating coil in which low-pressure steam was highly superheated. From the coil the steam entered a steam jacket. The retort with the coal was within this steam jacket. The retort was perforated so that the steam had free access to the coal. From the retort a pipe led to a condenser. The tar, gas, and condensed steam then flowed to a wash bottle, from which the gas was led to a gas holder.

Two difficulties arose in the use of this apparatus. In the first place, it was not possible to get sufficient heat to the coal, even though auxiliary burners were used to heat the retort and the superheating coils were kept at a dull red heat. This difficulty could have been easily overcome, however, by the use of more insulation so as to better conserve the heat. The other

difficulty was that the water and tar would not separate by gravity, even though left undisturbed for weeks at a time. Since at best the volume of water would be several times the volume of the tar, it seemed best to change to a type of apparatus where this difficulty would not be met.

While using the first apparatus one interesting characteristic of the coal was noticed. In one of the tests sufficient heat was secured apparently to fuse completely about two inches of coal on the bottom of the retort. The coke had a volatile matter content of 34.14 per cent. It was quite friable and burned with considerable smoke. This, together with other observations of a like nature, indicates two things: First, that the coal fuses before a large amount of the volatile matter is driven off; and

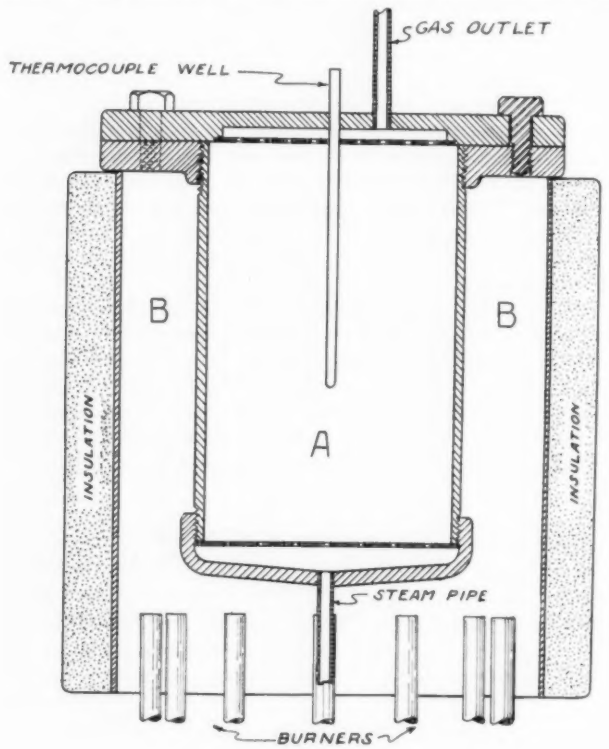

FIG. 1 THE RETORT

second, that exceedingly low temperatures will not produce a semi-coke hard enough to stand handling.

The apparatus finally used is shown in Fig. 1 and was built out of pipe fittings. The retort *A* is a piece of 4-in. pipe. On the lower end is a pipe cap, in the center of which a hole is drilled and tapped for the steam pipe. A plate with a large number of small holes is fitted in the lower end of the retort. This arrangement permits steam to enter the retort and be evenly distributed. At the same time the cap keeps the lower end of the retort from being overheated.

A flange is fitted on the upper end of the retort. A blind flange fastened to it by eight cap screws has a recess cut in its lower face in which a perforated plate is inserted, leaving a space above the plate as shown. The gas comes through the holes in the perforated plate and goes out through the gas line which leads from this space. A tube also protrudes through the plate into the retort. The thermocouple is placed in this tube. Other holes through both of the flanges permit the escape of the flue gases from the heating burners. The retort *A* is placed in the heating chamber *B*, which is well insulated. The heat is applied by the burners as shown in the figure.

In the first tests with this apparatus superheated steam was supplied through the steam pipe until the steam would blow through the gas outlet. In later tests the apparatus was used without steam.

The gas line extended to a bottle placed in cold water (Fig. 2). This gas line and cooled bottle acted as a condenser. The tar was deposited in the bottle and the gas passed on to a gas holder.

At the end of each run the gas was carefully measured and the reading of the meter corrected to reduce it to an equivalent volume at 60 deg. fahr. and 30 in. of mercury pressure. The tar was distilled and separated into various fractions as indicated later.

The carbonizing temperature was a maximum of 1000 deg. fahr. It took approximately three hours to reach this temperature. While the apparatus was designed for the use of steam, the tests here recorded were made without steam. Experiments with steam were not successful, but the condensing apparatus is being rearranged and other tests are to be made with the use of steam.

SUMMARY OF TESTS (10 TESTS)

Semi-coke per ton of coal			1393 lb.
Gas per ton of coal			3613 cu. ft.
Dehydrated tar per ton of coal			37 gal.
1	Dehydrated Tar:		
	a	Viscosity at 100 deg. fahr.	525
		at 210 deg. fahr.	40
	b	Specific gravity	1.04
	c	Flash point	140 deg. fahr.
	d	Burning point	175 deg. fahr.
	e	Heating value per lb.	16,600 B.t.u.
2	Dehydrated Tar, Less Oils to 100 Deg. Cent.:		
	a	Viscosity at 210 deg. fahr	49
	b	Specific gravity	1.06
	c	Flash point	255 deg. fahr.
	d	Burning point	280 deg. fahr.
	e	Heating value per lb.	16,500 B.t.u.
3	Dehydrated Tar, Less Oils to 225 Deg. Cent.:		
	a	Viscosity at 210 deg. fahr.	1570
	b	Specific gravity	1.089
	c	Heating value per lb.	16,400 B.t.u
	d	Flash point	312 deg. fahr.
	e	Burning point	350 deg. fahr.
4	Pitch at 290 Deg. Cent.:		
	a	Melting point	111 deg. fahr.
	b	Specific gravity	1.120
	c	Twist point	75 deg. fahr.
5	Pitch above 325 Deg. Cent.:		
	a	Melting point	450 deg. fahr.
6	Tar Products:		
	Motor fuel (0 to 210 deg. cent.) per ton of coal		4.4 gal.
	Burning oil (210–270 deg. cent.) per ton of coal		4.6 gal.
	Light lubricating oil (270–325 deg. cent.) per ton of coal,		4.4 gal.
	Heavy lubricating oil (325–350 deg. cent) per ton of coal,		2.8 gal.
	Grease per ton of coal		12 lb.
	Pitch per ton of coal		90 lb.
	Tar acids (phenol and cresols) per ton of coal		22 lb.
	Heavier tar acids per ton of coal		44 lb.
	Heating value of motor fuel per lb.		18,480 B.t.u.
	Specific gravity of motor fuel		0.833
	Heating value of burning oil per lb.		18,172 B.t.u.
	Specific gravity of burning oil		0.905

USE OF PRODUCTS

The coke produced is easily ignited and burns with a short blue flame. It burns without smoke even in an open grate. The grate fire has a very pleasing appearance. The semi-coke should find a market as a domestic fuel, since it takes no special appliances or procedure to use it. It is not an artificial anthracite; its density is much less. If used in stoves or furnaces designed

for anthracite, the semi-coke would require more frequent firing.

The gas was not scrubbed to remove light oils. If such scrubbing were done, about three gallons of light oil per ton of coal would be expected. This would reduce the value of the gas but would very greatly increase the amount of motor fuel recovered. The gas has a heating value of approximately 1000 B.t.u. per cubic foot. It is very high in luminants. The most obvious use of such a gas would be as an enriching agent for mixing with a lean gas such as water gas.

The tar might be used in several different ways. The large amount of tar acids suggests that they should be removed and used as preservatives for timber, as disinfectants, or as one of the raw materials for making such materials as bakelite. Other uses for the tar acids would be as raw materials for making explosives, dyes, and medical compounds.

The light oils both from the tar and that which could be recovered from the gas would make an excellent motor fuel. The lubricating oils and greases would be used as similar products from petroleum are used. The pitch could be used as the pitch from high-temperature tar is used.

Under present conditions the removal of the motor fuel and then the use of the remainder of the tar as liquid fuel for burning under boilers or for Diesel-engine fuel seems the most probable way of employing it. It is easy to paint pictures of the wonderful possibilities of coal tar as a raw material for the chemical industries, and its use in such a way is likely to increase rapidly in the future. Further tests will likely show that low-temperature tar is more suitable for that purpose than high-temperature tar. But the fact remains that at present a large part of the tar must find a use as fuel and the producer of low-temperature tar must expect that the large part of his tar will be used as fuel and will command the price it is worth in open competition with other liquid fuels.

A Laboratory Slagging Test for Boiler-Furnace Refractories

By R. K. HURSH,[1] URBANA, ILL.

This paper gives particulars of a simulative service test of refractories with coal-ash slag made in a laboratory furnace in which the test brick form the lining of a cylindrical chamber rotated about a vertical axis. Powdered slag or a mixture of slag with powdered coal is fed at a uniform rate through the gas burner which heats the furnace, impinging on the vertical faces of the brick and flowing out through the bottom of the furnace. Temperature and atmospheric conditions are controlled and the test brick receive equal slag treatment. Comparison of slag effect on the refractories is made by volume loss per unit area of exposed surface.

Tests have been made with slags representing coals used at five power stations where field tests were conducted, and the results are presented by the author. He finds that the relative effects of these different slags at a furnace temperature of 2900 deg. fahr. varies with the composition and fusibility of the coal ash. Further, the erosion of the refractory is dependent on the viscosity of the slag and increases in direct proportion to the furnace temperature. Tests made at temperatures corresponding to those in the boiler furnaces produce similar action on the refractories, as indicated by petrographic examinations. The relative resistance of refractories of different composition and physical structure is not the same for different slags.

IN AN INVESTIGATION of the slagging effect of coal ash on refractories, a laboratory testing method was sought which would determine the relative resistance of different bricks to such slags in terms which might be correlated with the results of service in boiler furnaces. The simulated service test was found most applicable for this purpose. Difficulty was found in obtaining equal heat treatment and uniform slag application on test bricks under conditions representative of boiler-furnace operation. A furnace[2] and a testing method have been developed which give a very satisfactory simulated service test.

THE LABORATORY SLAGGING-TEST FURNACE

General Description of Furnace

A general view of the furnace and its auxiliary equipment is shown in Fig. 1. A cylindrical furnace chamber is supported vertically on rollers and is rotated about its axis during the test. It is heated to any desired temperature with controlled atmospheric conditions by a blast burner using city gas and air, both at high pressure. Powdered slag is fed at a uniform rate through the burner and impinges with the blast on the vertical faces of the standard-sized test bricks which form the lining of the chamber. The melted slag flows down over the faces of the bricks and out through a port in the middle of the furnace bottom.

By rotating the furnace, each test brick is brought successively and repeatedly into position before the burner. Identical temperature conditions and uniform slag treatment for the several bricks are thus insured. A close control of both temperature and furnace atmosphere can be maintained to simulate conditions in the boiler furnace.

Furnace Details

Details of the furnace and equipment are shown in Fig. 2. Sixteen test bricks T are set on end with the $2^1/_2$-in. × 9-in. faces lining the chamber. These alternate with special arch bricks U to form a circle of $14^1/_2$ in. inside diameter. The lining is carefully laid up with thin mortar joints of fireclay and fine grog. The lining is backed by $2^1/_2$ in. of silo-cel brick placed on end inside the steel jacket E.

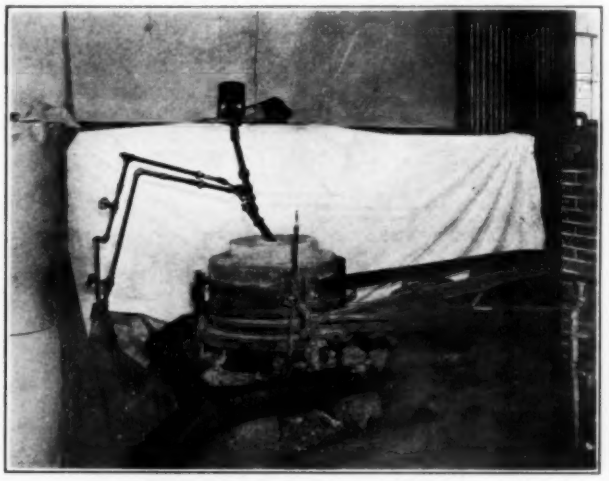

Fig. 1 Exterior of Slagging-Test Furnace

The bottom blocks of the chamber are supported by a cast-iron tire rim C and eight radial arms A. A hole 5 in. in diameter is left in the center for outflow of the melted slag.

The furnace is supported on rollers and is rotated at 13 r.p.m. by means of a belt passing around the steel belt band B. A series of guide rollers hold the furnace in position on the supporting rollers.

In order to protect the rollers from the heat of the gases and the melted slag at the bottom of the furnace, an octagonal screen of insulating blocks I is fastened to the supporting piers and channels. The rollers are also cooled by an air blast from a 12-in. sirocco fan through four branch pipes on a main air pipe surrounding the furnace. Further cooling of the furnace jacket, belt band, and tire rim is effected by a spray of water from a hose nozzle on the furnace jacket. This also protects the belt from excessive heating.

Slag from the bottom of the furnace is quenched in a drip pan placed between the supporting piers. A constant water level is maintained in the pan by a stream from valve Z. The regulation

Contributed by the A.S.M.E. Special Research Committee on Boiler-Furnace Refractories and presented at the Rochester Meeting, Rochester, N. Y., May 13 to 16, 1929, of The American Society of Mechanical Engineers. (The results herein presented are a part of an investigation conducted by the Engineering Experiment Station of the University of Illinois, of which M. S. Ketchum, Dean of the College of Engineering, is the director, and in the Department of Ceramic Engineering, of which Prof. C. W. Parmelee is the head. The work is being done in cooperation with the Special Research Committee on Boiler-Furnace Refractories of The American Society of Mechanical Engineers, of which Mr. C. F. Hirshfeld is Chairman.)

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of water level is necessary because of the cooling effect on the bottom opening of the furnace. Excessive cooling causes the slag to congeal and choke the slag exit.

The height of the furnace chamber is increased to $11\frac{1}{2}$ in. by a course of circle bricks V to permit placing the burner in such a position that the flame and slag will impinge at the desired height on the test bricks. A crown block W is provided with a 5-in. hole

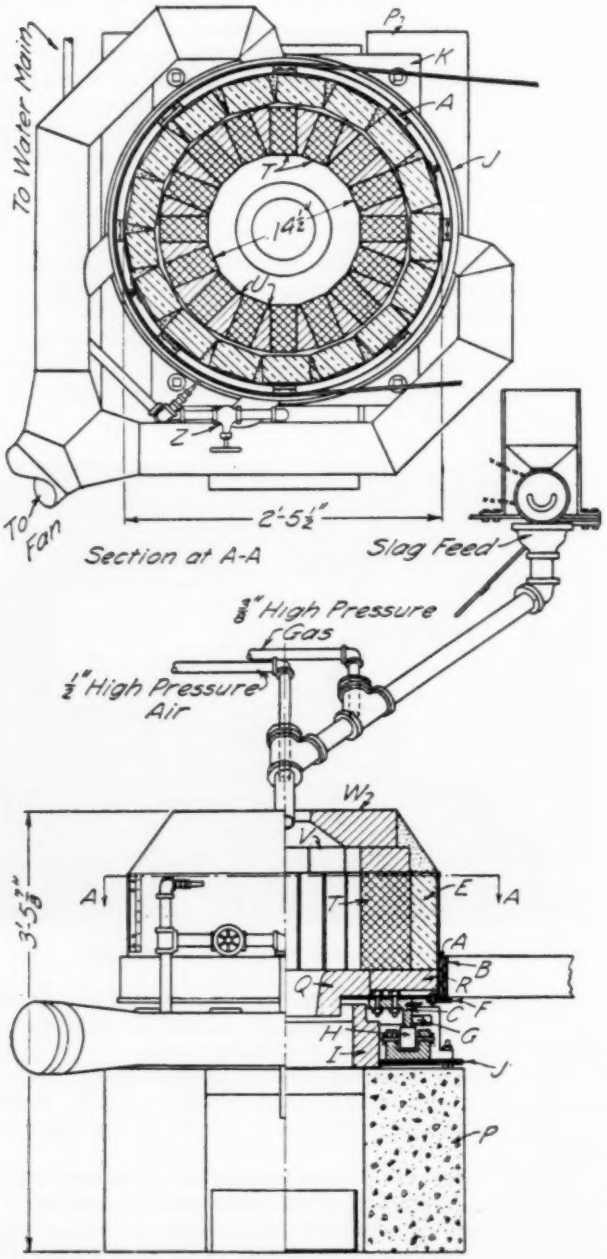

FIG. 2 DETAILS OF SLAGGING-TEST FURNACE

in the center which flares out to 12 in. on the underside to permit proper direction of the flame. The crown block is carefully centered in setting up the furnace for a test to insure uniform flame and slag impingement on all the bricks.

FEEDING OF SLAG

It is required that the burner shall deliver an adequate and properly proportioned mixture of gas and air and at the same time serve as a nozzle to direct a continuous stream of powdered slag against the faces of the brick. The burner is made up of standard pipe fittings. High-pressure air is supplied through a $\frac{3}{8}$-in. nozzle inside the upper $1\frac{1}{2}$-in. Y and, by its inspirating effect, draws in additional air through the slag feed opening above. City gas, at 10 lb. pressure, is supplied through a $\frac{1}{2}$-in. pipe which projects through the lower $1\frac{1}{2}$-in. Y into the mixing nozzle of the burner. The powdered slag, fed into the upper pipe, is carried in suspension by the air and gas mixture and is projected with the flame on the faces of the test bricks.

The slag, ground to pass a 40-mesh screen, is fed to the burner by a small screw feeder from which it discharges through a slot at one end. The screw, a $\frac{3}{4}$-in. shaft with a round-bottom thread of $\frac{1}{2}$ in. pitch, is driven at a fixed speed, ranging from 20 to 40 r.p.m., by a roller chain from a worm-gear speed reducer which is belted to a $\frac{1}{8}$-hp. motor. The speed of the screw is regulated to give a desired rate of slag feed.

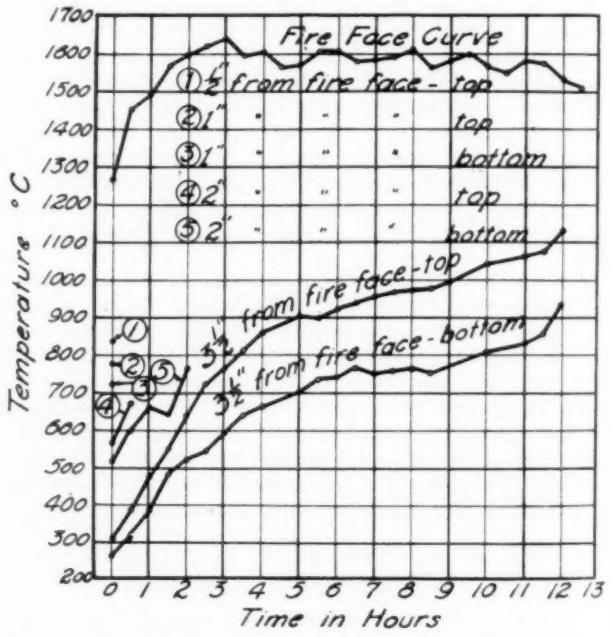

FIG. 3 TEMPERATURES IN TEST BRICK

TESTING PROCEDURE

The furnace is heated, while rotating, to a determined temperature before slag is introduced. This temperature is then maintained for a period of 24 hours during which slag is fed at a constant rate through the burner. Temperature readings are taken by means of an optical pyrometer sighted on the middle of the face of the test brick.

Gas samples are taken by means of a water-cooled sampling tube inserted through the top opening of the furnace. Atmospheric conditions can be varied over a considerable range, but can be maintained fairly constant with either oxidizing or reducing conditions. It is customary, in these tests, to maintain slightly reducing conditions to correspond with ordinary gaseous atmospheres in contact with the walls of boiler furnaces.

The temperature gradient through the test brick can be determined by inserting thermocouples at different depths when building up the lining, passing the leads out through the joint in the jacket. The rotation of the furnace is stopped while readings are being made. The curves in Fig. 3 show such readings taken during one of the tests. Variation of the temperature gradient

can be effected by changing the character or amount of insulation backing the test brick.

The interior of the furnace at the end of a test is shown in Fig. 4. Three bricks each of five brands were used in this test.

Measurement of Test Brick

The volume of each test brick is measured before and after testing by means of a mercury balance.[3] Depressions or irregularities along the edges of the slagged bricks, due to chipping while removing them from the furnace, are filled with plastic clay before making the final volume measurement. The difference between the initial volume and the residual volume after testing is taken as the loss due to slag erosion. Some error is involved in this due to shrinkage of the brick during the test. This increases the apparent erosion to a slight extent, but it is offset by the volume of the slag layer on the face of the brick, for which no correction is made. The slag layer, however, is in no case of very great thickness in these tests. The furnace temperature is usually maintained for 15 min. after the end of the slagging period to allow excess slag to run off and so minimize the error in measurement of erosion loss.

To eliminate errors in comparison of erosion loss due to variations in size of bricks the results are given in terms of cubic centimeters loss per square centimeter of exposed face. Comparative ratings of different brands of brick may be made by the ratio of their unit losses to that of some brand adopted as a standard for such comparison.

TEST WITH COAL–ASH SLAGS

Slag has been prepared from the ash of coals used at several plants at which studies of the furnace operation were made by the U. S. Bureau of Mines. Samples of the coals were burned on a hand-fired grate at the laboratory, and the cinder collected and ground to pass 20-mesh. The slags so prepared were used for tests in which refractories were included which were in use at the respective plants during the field tests.

It has been found desirable in some of these tests to use a mixture of equal parts of the coal ash and of the pulverized coal from which it was prepared. By use of this mixture, a higher concentration of reducing gases could be maintained in the furnace during some of the tests. Comparison of the effect of different atmospheric conditions on the slagging action could thus be made over a greater range than was possible with coal ash alone. To make these tests comparable with those in which only the slag was fed through the burner, the amount of coal and slag mixture was made sufficient to supply the same weight of ash as in the cases of slag alone.

A comparison of the analyses of the slag prepared for the laboratory tests with those of the coal ash obtained at the time of the field tests is shown in Table 1. All the analyses were made at the U. S. Bureau of Mines Laboratories. Softening-point determinations of the laboratory slags are also shown under both oxidizing and reducing conditions. In the latter determination the atmosphere was maintained at practically the same conditions as in most of the slagging tests.

There is a close similarity in the analyses of laboratory and field samples of ash from the Lowellville, Cleveland, and Cahokia coals. In the case of the East Peoria material the laboratory ash shows higher contents of SiO_2 and CaO with less Fe_2O_3 than the field sample. The variation is probably not greater than occurs regularly in sampling of this coal, and is not considered to be of any special significance in test results.

The two samples from the Chicago station show very decided

Fig. 4 Interior of Furnace After Test

differences. At the time the coal was sent for laboratory tests there was some question as to whether or not it corresponded to the coal used during the field tests. It was evident that the laboratory sample did not represent the usual slag in these furnaces since it was much less fusible and its action on refractories was much less severe than was to be expected. A later sample of coal from the same station was of an entirely different character and conformed to expectations in its action in the slagging tests.

In a majority of the laboratory tests a temperature of 1600 deg. cent (2912 deg. fahr.) has been arbitrarily chosen for the slagging period. This relatively high temperature was adopted to produce a considerable amount of erosion of refractories in a period of 24 hours. It is not desirable to extend the time for a laboratory test much beyond this period. Since the temperature selected exceeds that in most of the boiler furnaces, the question may be raised as to whether or not laboratory results would fairly represent those of service. The slagging action will be definitely more severe at the higher temperature, but results indicate that, for comparing the slag resistance of different refractories, the higher

[3] A. E. R. Westman, *J. Am. Cer. Soc.*, vol. 9 (1926), p. 311.

temperatures give more distinct differences in erosion loss but in much the same relative proportions as the lower temperatures.

Relative Effects of Different Slags

The results of tests with slags from the different coals, at approximately the same temperature and atmospheric conditions, are shown in Table 2. Test No. 23 was made with ash from Chicago coal which did not correspond with that used in the field tests. The ash used in test No. 30 was from a second lot of coal which came from the same mine as that used during the plant tests. The difference is quite evident in the relative effect on the refractories.

The erosion losses of brick of the different brands is low for the Chicago No. 1, Pennsylvania-Ohio, and Cahokia slags at 1600 deg. cent., intermediate in value for the Cleveland, and high with East Peoria and Chicago No. 2 slags. Both of the last named show high CaO content as compared with the others. Both of these slags were much more fluid than the other samples at 1600 deg. cent. They attacked the brick much more vigorously and tended to cause channeling in the eroded faces to a much greater extent than the others.

The Cleveland slag was somewhat less fluid than the East Peoria and Chicago No. 2 slags, but much more so than that from the other coals. While the Fe_2O_3 content is much the highest of the group, the CaO content is intermediate between the high-lime and low-lime slags. The erosion losses due to the Cleveland slag are somewhat lower than those of the East Peoria and Chicago No. 2 tests, but much in excess of the other three.

The three slags showing the low erosion effects vary considerably in the contents of Fe_2O_3 and CaO, but are similar in the content of SiO_2, which is well above that of the slags which showed greater erosive effects. The Al_2O_3 content of these three slags is also somewhat above that of the more fluid slags. The high SiO_2 content would greatly increase the viscosity of the slags, and even small increases in Al_2O_3 should aid in this effect. In general, the erosive effects of the slags may be said to correlate with the chemical composition and with the fluidity at the furnace temperatures.

It was noted that the results of the laboratory test, as regards the relative erosive effects of slags from East Peoria and Cahokia coals, did not correspond to the observed conditions during the field tests. At the East Peoria station little trouble was encountered due to slagging of the furnace walls, while at Cahokia the slagging effect of the ash was severe. The ash analyses show that the fused ash from Cahokia coal should be much more viscous than that from East Peoria, and there is also a difference of 260 deg. fahr. in the softening temperatures. Hence, the foregoing results probably reflect very well the relative activity of the two slags under like operating conditions.

In normal furnace operation at the two plants, it is shown by Sherman and Taylor[4] that the gas temperature near the wall face at the point of maximum erosion was 2750–2780 deg. fahr. in the Cahokia furnace and 2050–2420 deg. fahr. in the East Peoria furnace, an average difference of around 500 deg. fahr. The atmospheric conditions in the East Peoria furnace were only very slightly reducing, with less than 1 per cent CO, while the gases in the Cahokia furnace showed approximately 4 per cent each of H_2 and CO. These differences in operating conditions are sufficient to account for the apparent discrepancy in the behavior of the two slags.

The appearance of bricks from the tests listed in Table 2 with the six different slags is shown in Figs. 6 and 7. The marked difference in effect of the two slags from Chicago coal is quite evident. The high viscosity of the ash from the Lowellville coal has produced an appreciably thicker slag coating than that of the more fluid slags.

Effect of Temperature on Slag Action

The results of tests made with three coal-ash slags at different slagging temperatures are shown in Table 3. In each case the lowest temperature used approximates that reported as the average in normal operation at the respective plants. A test with the East Peoria slag at 2400 deg. fahr. was not completed due to a furnace breakdown after 7½ hours' operation.

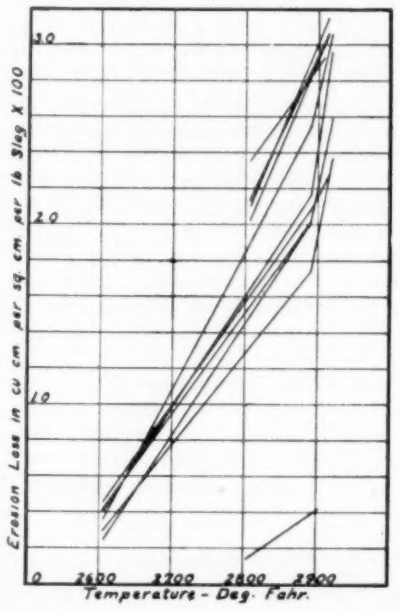

Fig. 5 Effect of Temperature on Erosion by Slags

To better simulate service conditions, the tests with Cahokia slag were made with more strongly reducing conditions. This necessitated the use of a mixture of equal parts of powdered coal and coal ash. The rate of feeding was increased so as to introduce approximately the same amount of actual slag as in previous tests with powdered slag alone.

The amount of erosion loss in the case of each of the slags increases rapidly as the furnace operating temperature is raised. A study of the relationship between the viscosity of coal-ash slags and temperature should be of interest in this connection. It is apparent that the viscosity is a primary factor in the relative erosion of the refractories at different temperatures. A rough

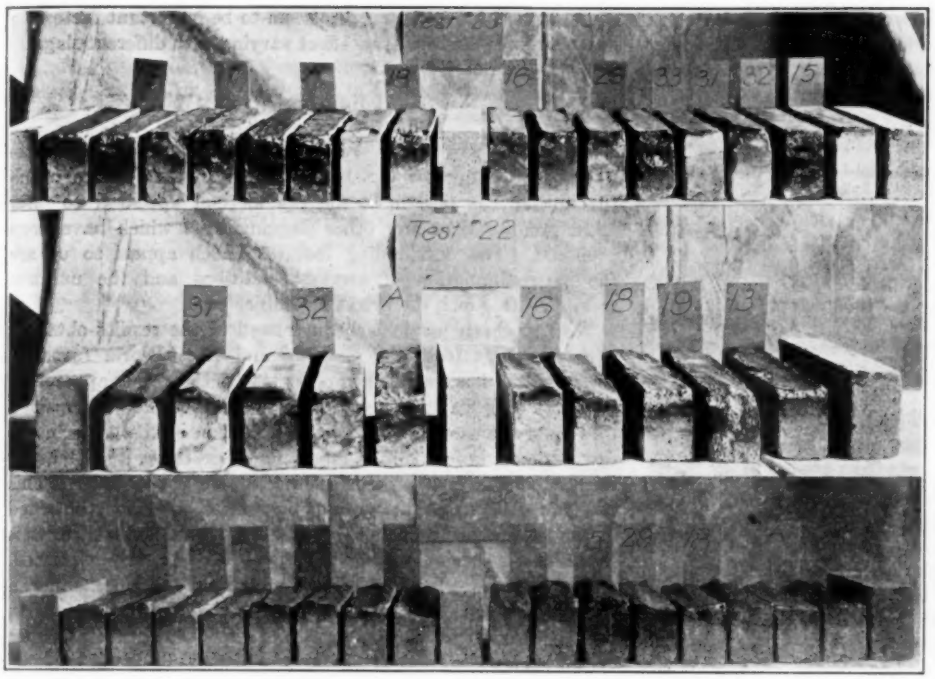

FIG. 6 COMPARATIVE EFFECT OF SLAGS

comparison of the effects on several brands of firebrick is shown by the curves in Fig. 5 for the three slags. The erosion losses of the bricks given in Table 3 have been calculated as cubic centimeters per square centimeter of exposed face per pound of slag fed to the furnace. Tests at one or two additional temperatures will show whether the relation is linear or parabolic in character.

It is apparent from these data that for each slag there is a definite temperature below which the slag will build up on the refractory without producing an appreciable amount of erosion. This temperature will depend directly on the composition of the slag and its viscosity-temperature relationship. A study of the viscosities of coal-ash slags at different temperatures should be of considerable interest in this connection.

EFFECT OF FURNACE-GAS COMPOSITION

The comparative effects of slag action with different degrees of reducing conditions in the furnace gases have not yet been determined. It has been shown[5] that in softening-point determinations on coal ash the furnace atmospheric conditions have a very appreciable effect due to reduction of Fe_2O_3 to FeO. At the higher temperatures encountered in boiler furnaces and in these tests the effect may not be so marked, since a part of the iron of the slag is in the ferrous form due to the equilibrium conditions between FeO, Fe_2O_3, and O_2 at these temperatures. Further tests are to be made with differing atmospheric conditions.

[5] A. C. Fieldner and A. E. Hall, "The Fusibility of Coal Ash and the Determination of the Softening Temperature." Bull. 129, U. S. Bureau of Mines (1918).

COMPARISON OF TEST RESULTS WITH SERVICE RESULTS

Microscopic examinations have been made of thin sections from bricks subjected to the laboratory tests along with samples of the same brands taken from furnaces during the field tests. These have been compared to determine the similarity or dissimilarity in the crystalline phases appearing in the slag coatings and at the slag contact on the bricks. Similarity in this respect would indicate that the conditions in the laboratory test were sufficiently like those in the boiler furnace to make the results of the laboratory tests comparable with service conditions.

In a progress report Rexford[6] states that "The field samples all contain much mullite and small quantities of minor minerals, particularly magnetite. The test samples also contain mullite, but rarely show any minor minerals except a little magnetite at

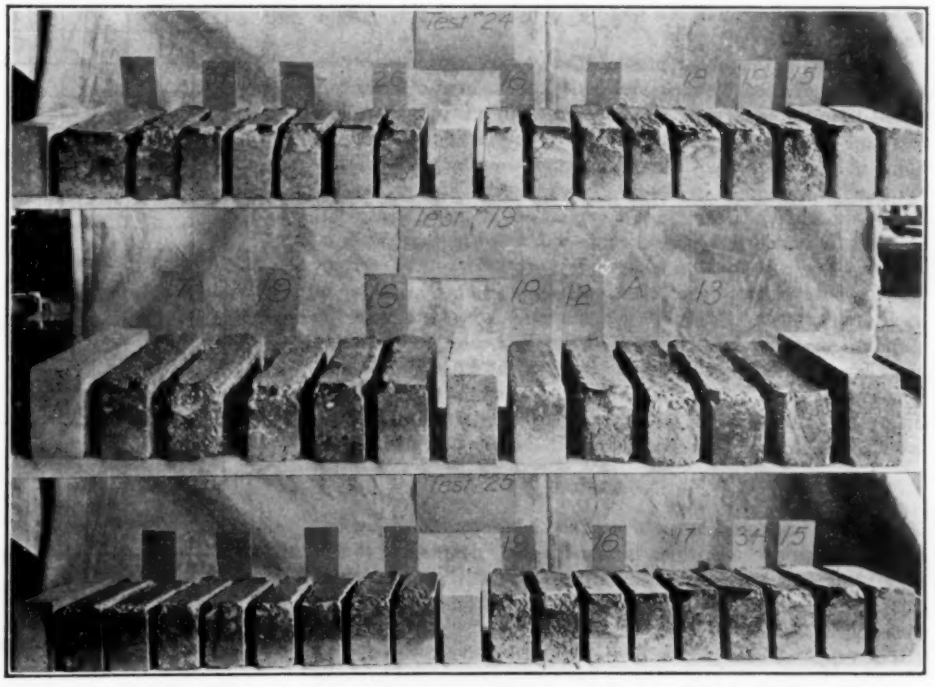

FIG. 7 COMPARATIVE EFFECT OF SLAGS

times. So, in general we may say that, for all practical purposes, the test furnace is duplicating the field service so far as the slag formation is concerned unless the minor minerals have considerably more importance than is apparent at present."

TABLE 4 RELATIVE RATING OF REFRACTORIES BY COMPARISON WITH BRAND 18

Slag used	—Chicago No. 2—			—East Peoria—			—Cleveland—		
Test No.	28	30	Avg.	18	19	Avg.	21	22	Avg.
Brand				Dry Pressed Brick					
18	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00
19	1.12	0.93	1.02	1.05	1.14	1.10	0.90	0.99	0.94
9	1.02	0.98	1.00	1.25	1.26	1.25	0.96	0.96	0.96
				Stiff Mud Brick					
21	0.93	0.97	0.95	1.01	0.95	0.98	1.19	1.12	1.15
13	0.93	0.98	0.95	0.85	0.90	0.87	1.02	1.26	1.13
				High-Alumina Brick					
15	0.93	0.77	0.85	1.00	1.01	1.00	0.51	0.59	0.55
17	0.95	0.89	0.92	1.06	1.29	1.17	0.60	0.70	0.65

Comparison of the East Peoria field samples with those of the laboratory tests showed a discrepancy which was undoubtedly due to higher temperature in these tests than existed in the boiler furnace. Examination of samples from the incomplete test at 2400 deg. fahr., with this slag showed crystalline development very similar to that in the field samples. This temperature approximates the average gas temperature near the side wall in the field tests. Hence it appears that the same crystal phases appear in the cooled laboratory-test slags as in those from the boiler furnace when the operating temperatures are the same.

Comparison of Refractories

Comparison of the resistance of different refractories may be made by reference to some one brand as a standard. For present purposes, bricks of brand 18 were selected as a basis of comparison since these brick appeared to be quite uniform in quality and in their resistance to slagging action. The data in Table 4 show the average losses of two bricks each of several brands in tests with three different coal-ash slags. These tests were selected because the amount of erosion produced during the period of the test was sufficient to give comparative losses. In tests with more refractory slags the erosion was so slight that a fair comparison of the resistance of different bricks was not obtainable in the 24-hour slagging period.

Each figure in the table represents the average loss of two bricks of a brand divided by the average loss in volume of bricks of brand 18 in the same test. Ratings less than unity indicate less loss and better resistance than that of the comparison brand. Some of the refractories show considerable variation in the resistances of individual bricks to a given slag. This may be due to non-uniformity in structure, composition, or firing treatment.

There is evidently a considerable difference in the effects of different coal-ash slags on a given type or brand of refractory, which would indicate that chemical composition is a factor of some importance. Bricks of higher alumina content than the standard flint-clay refractories show much greater resistance to the Chicago and Cleveland slags than to the East Peoria slag. The structural character of stiff-mud bricks seems to be a factor of greater importance in the case of East Peoria coal ash, which is notably high in lime content, than in that of the Cleveland slag.

CONCLUSION

The data presented indicate that the laboratory slagging test reproduces service conditions to a satisfactory degree and that it may be used as a means of comparing the relative resistances of different types of refractory to the slagging action of coal ash in boiler furnaces.

The range of composition and structural character of the refractories included in these tests is not sufficient to give a basis for general conclusions as to the relative merits of the different types. Both composition and structure seem to be important factors in slag resistance, their relative effect varying with different slags.

Discussion

Ralph A. Sherman.[7] We of the Bureau of Mines have followed with much interest the tests with the furnace which the author has described, for the method appeared to offer more promise than any other slagging tests which have been proposed. The outstanding features which appeal to us are the close simulation of service conditions and the uniform treatment to which the bricks are subjected.

We have been particularly interested in the results obtained with the slags from the Cahokia and East Peoria furnaces. As the author has stated, the first runs with these slags apparently showed a discrepancy between the operating and the test results, but when the temperature and composition of the gases in the test furnace were made comparable with those in the boiler furnace, the degree of erosion was in the right order. This illustrates the value of the data on service conditions obtained in the field phase of this investigation, for without them it is doubtful whether this could have been satisfactorily explained.

Another point which is forcibly brought out is the manner in which a few changes in furnace design at the East Peoria station brought about satisfactory costs of brickwork maintenance even with an extremely erosive ash. The results of the author's

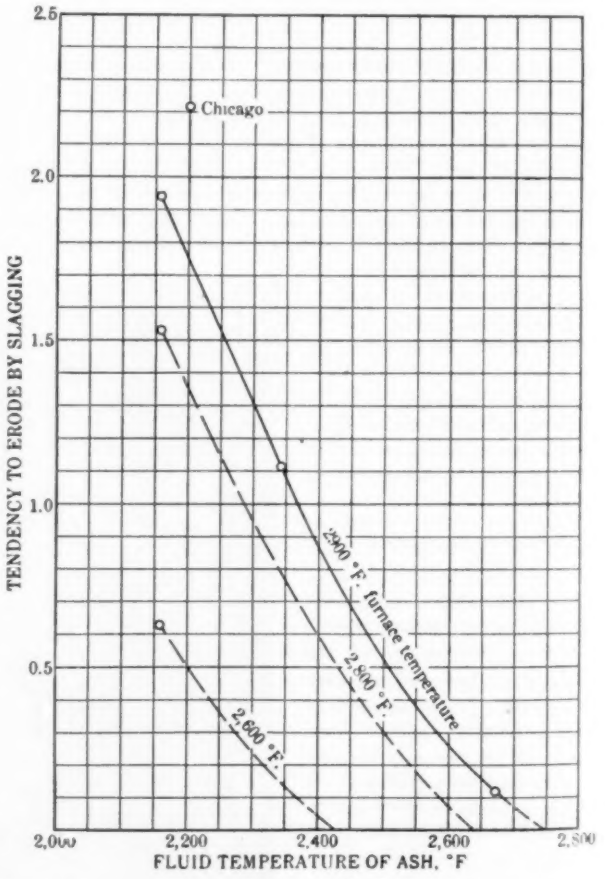

Fig. 8 Tendency of the Ash of Coal to Erode Plotted Against the Fluid Temperature of the Ash

[7] Fuel Engineer, Pittsburgh Experiment Station, U. S. Bureau of Mines, Pittsburgh, Pa. Assoc-Mem. A.S.M.E.

tests indicate that at similar temperatures the erosion by the East Peoria slag would be two to three times as great as by the Cahokia slag, but the actual erosion at East Peoria was made less instead of greater than that at Cahokia by slight changes in the design of the burner, by changes in the design of the ports for the admission of secondary air, and by the introduction of air at the side wall through ports in the burner arch, all of which did not lower the combustion or boiler efficiency.

Another point of interest, particularly with the Cahokia slag, is the great difference in the erosion caused by a change in temperature of but 100 deg., and illustrates the care which an operator must take to remain within safe operating limits.

P. NICHOLLS.[5] With our present limited knowledge of the relation between viscosity, temperature, and the chemical analysis of coal ash it is doubtful whether one could safely predict the probable slagging effect of a given coal from its ash analysis alone. Although doubt is sometimes cast also on the reliability of the values given by the standard gas-furnace fusion test, yet it is the most used method, and its values for most coals are available; it is also to some extent a direct measure of viscosity. It would therefore seem logical, for the time being at least, to attempt to relate the tendency of a coal to slag to its ash-fusion temperatures.

This was done from the data given in the paper. It was assumed that the data given in Table 1 for the laboratory sample of the Chicago ash were for what is called Chicago No. 1 and that those for Chicago No. 2 are not included, but if the ash were similar to that collected in the field the values would be: Softening temperature, 2000 deg. fahr.; softening interval, 60 deg. fahr.; fluid interval, 200 deg. fahr. Plots showed that the fluid temperature gives a more consistent curve for the quantity of slagging than does the softening temperature; this would be expected because the softening temperature represents a comparatively high viscosity. Each type of brick would have its own slagging-fluid temperature curve, but the paper shows that the variations are not extreme and the curves of slagging against face temperature tend to be parallel. One can therefore speak of the tendency of a coal ash to slag independent of a particular refractory.

In Fig. 8 the tendency of an ash to erode by slagging is plotted against the fluid temperature of the ash. Only values from the author's tests having the same reducing atmosphere of about 2.5 per cent CO were used. There are several points to fix the 2900 deg. fahr. temperature of the surface; the point for the Chicago coal on the assumed fluid temperature of 2200 deg. fahr. is shown, but it is not included in the curve. There is only one point each for the 2800 and 2600 deg. fahr. wall-face temperatures, and the dotted curves indicate the form one might expect these curves to take.

It is not safe to generalize much from the limited data now available, but the establishing of such a relationship would be useful in judging the relative availability of coals; variations from such curves would be expected, but the knowledge of prevailing furnace conditions in a particular furnace will rarely be exact.

The new tool developed at the University of Illinois should prove very useful not only in the study of refractories but also to coordinate data from laboratory studies of coal ashes and slags with this larger scale application.

AUTHOR'S CLOSURE

Dr. Nicholls has pointed out an apparent relationship between the fluid temperature of a coal ash and its comparative slagging effect on refractories that merits further study. A general relationship would be expected since the fluidity of the slag is of primary importance in its action on firebrick. When data for individual brands of firebrick are plotted, as in Fig. 8, the curves will be found to flatten out at the higher temperatures. There is also some question whether the points for the East Peoria slag fall in line satisfactorily with those for the other coal ashes. This ash was exceptionally high in CaO, and its comparative action on different brands of brick was not in the same order as that of other slags. Some classification of ashes with respect to their chemical compositions might be necessary in applying the correlation suggested.

FSP-51-45

A Study of Crystalline Compounds Formed in Slags on Boiler-Furnace Refractories[1]

By T. A. KLINEFELTER[2] and E. P. REXFORD,[2] COLUMBUS, OHIO

For several years the action of boiler-furnace refractories under various service conditions has been investigated. The present method of investigation used by the Bureau of Standards at Columbus is similar to that used by the Geophysical Laboratory in studying the lime-alumina-silica system, with the addition of iron. It is known as the quenching method. The apparatus consists of two furnaces, a preheater and a quenching furnace automatically controlled. The length of time required for each melt depends on its composition. Each melt determines an equilibrium point, a number of which are necessary for determining the point sought, i.e., the temperature at which the primary phase for that composition disappears and the charge becomes a clear glass. A number of the latter points determine a surface known as an "isopleth." In working out the system one component is held constant, in this case iron, and the others are varied. In conjunction with the above, field slags, the data of which are known, are being quenched and their results compared with those of the component system.

The paper is a progress report of the work done to date, of the methods used and the difficulties encountered in a laboratory study of the equilibrium relation of oxides composing the slags on boiler-furnace refractories at high temperatures. No data or conclusions are presented.

FOR several years the action of slags on boiler-furnace refractories under different service conditions has been investigated cooperatively by the A.S.M.E. Special Research Committee on Boiler-Furnace Refractories, the University of Illinois, the Bureau of Mines, and the Bureau of Standards. A previous report[3] on this problem pointed out the necessity of a fundamental study of the system involving the principal components found in the slags formed on boiler settings.

When the general investigation started, chemical and petrographic analyses were made of slags sent in from various boiler settings, but these failed to give the desired information. Some further work was done by making mixtures similar in composition to the minerals found in the slags, and determining the fusion points of small cones prepared from them. Since the methods tried failed to give information on the course and rate of reactions between coal ash and clay refractories at high temperatures, a method believed to be satisfactory for the purpose was adopted. This method is similar to that used by Rankin and Wright[4] at the Geophysical Laboratory for the study of the lime-alumina-silica system. It is known as the quenching method, because samples having once reached equilibrium under a given set of conditions are chilled or frozen before a change of conditions due to cooling can affect the phases present in the sample. Phases which are crystalline at the temperature of equilibrium are crystalline at room temperatures, while those which are liquid at equilibrium temperature are glass at room temperatures. It was felt that this procedure would be all the more appropriate since slags in general contain lime, alumina, and silica as major constituents, and in addition significant amounts of iron oxide. Minerals containing other oxides such as magnesia and soda have been found in some of the slags, but usually in small quantities. Because the complexity of a system involving six or more oxides would increase the amount of work greatly, it was decided to limit the study to the lime, alumina, silica, and iron oxide. The system becomes five-component if both the ferrous and ferric forms of iron are present in these slags, as they probably are.

The apparatus is essentially that described in the article mentioned. It consists of two furnaces, one for preheating and the other for quenching the melt after equilibrium is attained, the latter being automatically controlled by a Roberts[5] temperature regulator.

The charge is sintered in the preheater, ground and resintered several times to insure complete uniformity, and finally introduced into the quenching furnace. The temperature in this furnace is carried well above the point at which equilibrium is to be established so as to insure complete fusion within a reasonable time. The furnace is then cooled slowly until the temperature is reached at which the quenching is to be made, and it is held at this temperature sufficiently long to make certain of complete equilibrium in the charge.

The length of time to attain equilibrium depends on the composition of the charge. Some of the high-silica charges require 6 to 8 hours, while others lower in SiO_2 require only 15 to 20 minutes.

At the proper time the charge is dropped from the furnace into a mercury bath, freezing or quenching it suddenly from the temperature to which it has been subjected. A microscopic examination of the chilled materials reveals the phases present before the charge was quenched.

Each of these melts determines an equilibrium point, since the phases are in equilibrium for that temperature and composition. We are particularly interested in the temperature at which the first crystalline phase (called the "primary phase") appears on cooling a charge of a given composition. This point cannot be predicted precisely, but may be obtained by using the method of trial and error. Three to fifteen equilibrium determinations are often necessary. Charges of the same composition are first heated to such high temperatures that they are completely liquid, then to successively lower temperatures, until a point is reached at which the primary crystalline phase first appears. This procedure is checked by heating charges, first at a rather low temperature, then at successively higher temperatures, until the last trace of the primary crystalline phase disappears. The final result gives a desired point on the solubility surface. By determining a sufficient number of these points and passing a warped plane through them, we obtain the solubility surface for this particular part of the system. Points above this surface represent solutions that are unsaturated with respect to the primary phase, while points below this surface represent saturated solutions.

Contributed by the A.S.M.E. Special Research Committee on Boiler-Furnace Refractories and presented at the Rochester Meeting, Rochester, N. Y., May 13 to 16, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

In working out a four-component system one component is held constant and the other three are varied. This gives us what might be termed a level ("isopleth," in physical-chemical terminology) with respect to the component held constant. After covering the triaxial field at intervals in this way, the component held constant is increased or decreased and again made a constant, and the other three are again varied so as to cover the field once more. We now have two levels with rather different contours.

In the system involving the slags in question, the first study was made with the iron oxide constant at 10 per cent by weight, and the anorthite, silica, and mullite varied to cover the field included by these three components. The work with 10 per cent iron oxide as the constant is nearing completion. Since the slags frequently contain higher percentages of iron oxide than 10 per cent, it will be necessary to work out several more levels before correct conclusions can be drawn.

Since adopting the quenching method, some of the earlier determinations made on the field slags have been checked. It has been found unsatisfactory to base conclusions on petrographic examinations of slowly cooled samples since the phases present in such samples are not necessarily those present at the operating temperatures. It is therefore more desirable to reheat the sample to the operating temperature at which it was formed, quench it, and then make the determination.

Another consideration of the greatest importance in this study is whether the iron oxide under operating conditions is present in the ferrous or ferric state. It is known in general that a highly reducing atmosphere greatly decreases the life of clay refractories. Reducing conditions cause the ferric iron present in the refractories to change to the ferrous state. We have some evidence that a slag high in ferrous iron develops very little mullite. Other evidence indicates that a slag containing a large quantity of mullite is more viscous. Because of its high viscosity the rate of flow and of corrosive action of this slag is relatively low.

To investigate this matter thoroughly it would be necessary to make all the equilibrium determinations first under highly oxidizing conditions and then to duplicate all of them under highly reducing conditions. The melts at present are made under oxidizing conditions, but it is almost impossible at times to prevent a certain amount of reduction due to the high temperatures. A determination of the ferric-ferrous iron ratio of the charges will undoubtedly give a number of cases with a high ferrous ratio and therefore some indication of the phases present in parts of the field under reducing conditions.

All the slags collected for test, except one, are normal boiler-furnace slags and may be considered as lying within the limits of the system under investigation. This one exception contains significant amounts of constituents other than lime, alumina, silica, and iron oxide. The operating temperature of the furnace in which this slag was produced was relatively low, a condition that may account for the fact that, although the slag contains no mullite, it does not corrode the refractory appreciably.

While the field under investigation does not cover this exceptional case, the work done so far does show definitely that the case is clearly outside the field, and also points out fairly clearly the direction in which the field of that slag lies.

The study of the system is fairly well started and is reaching a stage where, with the data from the field samples, explanations of some points are apparently indicated.

A brief description of the system being investigated and of the procedure involved has been given. It can readily be seen that the work is time-consuming, but the few results obtained justify the belief that further work will provide data of value in predicting the behavior of coal-ash slags of known composition when in contact with clay refractories at temperatures encountered during boiler-furnace operation. When this study of equilibrium conditions at high temperatures in this system is completed, it is hoped that it will be necessary only to know the approximate composition of the slags and the operating conditions, especially the temperatures and the character of the furnace atmosphere, to determine whether clay refractories will have a satisfactory life. On the other hand, wasteful service tests will not be necessary to ascertain if coal from a specified district may be used under the conditions obtaining in a furnace.

FSP-51-46

Heat-Insulation Practice in the Modern Steam-Generating Plant

By L. B. McMILLAN,[1] NEW YORK, N. Y.

This paper outlines briefly the engineering principles of heat-insulation design. Especial emphasis is given to the fact that the heat dissipated by so-called "radiation" losses is from the most valuable portion of the heat, and that these losses frequently result in the lowering of heat potential or temperature head, with a resulting loss in the value of all of the heat as measured by its remaining effectiveness.

A distinction is drawn between the cost of average heat and the value of a particular portion of the heat in terms of what it will accomplish in the way of useful results. The higher value of high-potential heat is demonstrated, and a specific evaluation in the case of heat in superheated steam used for power generation shows that the high-potential increments of such heat may be 1-1/2 or even 2 times as valuable as the average heat content of the steam.

Results accomplished by the insulation of various units of power-plant equipment are discussed and typical installations are shown.

The factors involved in determining the most economical thickness of insulation are discussed and a chart is given on which each of the factors may be taken separately into account. The resulting economical thickness may quickly and conveniently be determined directly from the chart.

THE insistent demand for higher economies has resulted in the devoting of the greatest care to the design and operation of steam power plants in order that, for the conditions of the particular installation, the maximum overall economy will be secured. A marked feature of this development has been the advent of steam temperatures and pressures, which only ten years ago would have been considered highly speculative. But these and many other revolutionary improvements in power-plant design have proved highly successful, and along with them heat insulation, always an important item, has become a still more vital factor in power-plant economy. And insulation is no longer treated as merely an incidental, but is made the subject of careful engineering design, just as are the other items in the more complex power station of today. The object of this paper, therefore, is to point out some of the more important features of heat-insulation design, and to present them in a manner conveniently useful to power engineers.

An outstanding feature of recent progress in the heat-insulation field has been the increasing realization of the fact that, large as they are, direct fuel economies are by no means the sum total of the beneficial effects secured by the minimizing of heat losses from heat-using equipment. In industry in general, greater attention is being given to the effect of insulation in increasing production through the maintenance of heat potential, in improving quality of product through the maintenance of greater uniformity of temperature, and in increasing the productivity of labor through the maintenance of improved working conditions in the vicinity of heated equipment.

Nor are these indirect effects lacking in the steam power plant. Results there may not be classifiable under the aforementioned three headings, but the insulation of pulverized-coal bunkers and piping to prevent caking of the coal due to condensation, and the insulation of turbine-room roofs, cold-air ducts and condenser-water piping to prevent the troublesome drip due to condensation of moisture from the air are typical examples of cases where there are other considerations which completely overshadow that of heat saving.

The Higher Value of High-Potential Heat

The power station furnishes also one of the most convincing examples of the value of the maintenance of heat potential. The heat conserved by insulation is the most valuable portion of the heat. It is the cream, so to speak; the high-potential heat that costs most to produce and that does the most effective work.

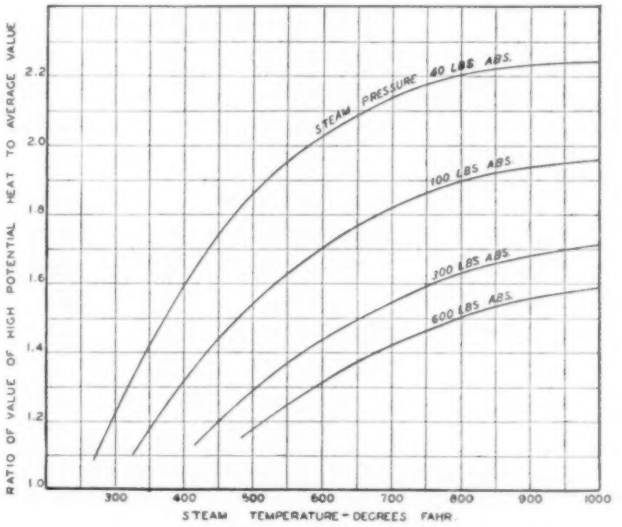

FIG. 1 RATIO OF VALUE OF HEAT AT STATED TEMPERATURE TO AVERAGE VALUE

(Based on expansion to condenser pressure of 1 lb. abs.)

Power engineers do not need to be told that a given number of B.t.u. at high potential will produce more power than the same number at lower potential; or that maintaining the required superheat will make all of the heat units more effective in the turbine than if dissipation of temperature head is permitted to degrade all of the heat; or that there is plenty of heat in the condensing water but useless because it lacks the required potential to make it capable of accomplishing useful work. But the attempt to evaluate the heat in terms of its potential is worth while, and seems not to have received the attention it deserves.

Fig. 1 represents the results of such an evaluation. It is at once apparent that in some cases the value of the last increment of heat at the top of a particular temperature range is between 50 per cent and 100 per cent greater than the average value for that range (the temperature range is that of the complete cycle from condenser temperature up to the given temperature). This is reasonable,

[1] Deceased. Formerly Consulting Engineer, Johns-Manville Corporation. Mem. A.S.M.E.

Contributed by the Power Division and presented at the Rochester Meeting Rochester, N. Y., May 13 to 16, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

because no extensive analysis is needed to show that the effectiveness of the last increment of heat in doing useful work must be much greater than the average when that average is penalized by the low effectiveness of the first increments of heat added in the cycle to water at condenser temperature. The availability of these first increments of heat in the cycle to do useful work is but

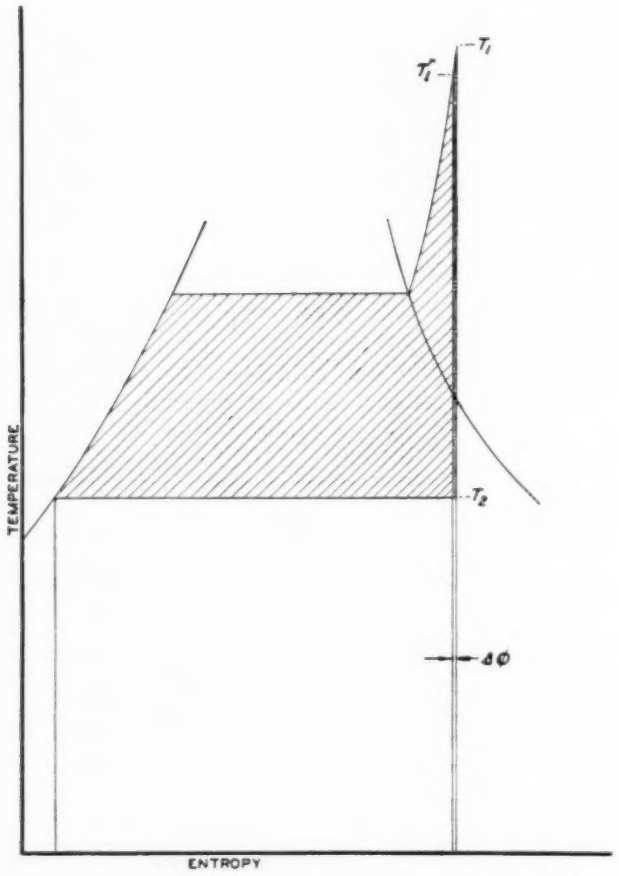

FIG. 2 TEMPERATURE-ENTROPY DIAGRAM OF STEAM-POWER-PLANT CYCLE

little above zero. Hence the average effectiveness must be lower than that of the last increment added at high potential. All of this is clearly obvious in the temperature-entropy diagram, Fig. 2, in which the area $[(T_1 + T_1')/2]\,\Delta\phi$ is the increment of heat which may or may not be lost by radiation and convection losses according to the effectiveness of the insulation. It will be noted also that the convertability of this increment of heat into useful work approaches that of the ideal cycle where efficiency is $(T_1 - T_2)/T_1$.

Furthermore, it may not be said that the value ratios in Fig. 1 are only theoretical. They are very conservative and intensely practical. No claim is made that the high-potential increment of heat is converted into work at ideal efficiency, but surely the inclusion of this increment *does not increase* nozzle losses, bucket losses, and windage. These items take a proportionately greater toll from the average than from the high-potential heat; therefore, for actual operating conditions the *ratios* in Fig. 1 are most conservative.

From Fig. 1 it will be noted that the relative value of the last increment as compared with the average value of heat decreases as the pressure is increased. This does not mean that the actual value of that increment is any less. It is the same, but since the average value of all of the heat is increased at the higher pressures, the ratio of value of the high-potential increment to the average is, of course, decreased.

It might be said that there is nothing new about this, and that the value of adding superheat to steam and of preventing excessive temperature drop has long been recognized. This is true, but temperature drop as such does not tell the whole story. It is commonly felt, if there are only a very few degrees drop from the superheater to the turbine, that the situation is satisfactory, and little thought is given to the dollar value of these few degrees when applied to literally billions of pounds of steam handled per year. When the dollar value is considered it usually is in terms of the fuel cost of the average and not of the high-potential heat. Yet it is this more valuable high-potential heat which figures in "radiation" losses—heat which would be available without further fuel cost, equipment cost, or operating cost.

The suggestion is sometimes offered that heat losses from equipment in power stations are not actually lost because they go to heat the building, to supply preheated air to the boiler furnaces, etc. But heat is not required to heat the building all of the time, and, still more important than that, such heat as is needed for that purpose can be obtained from bled steam having

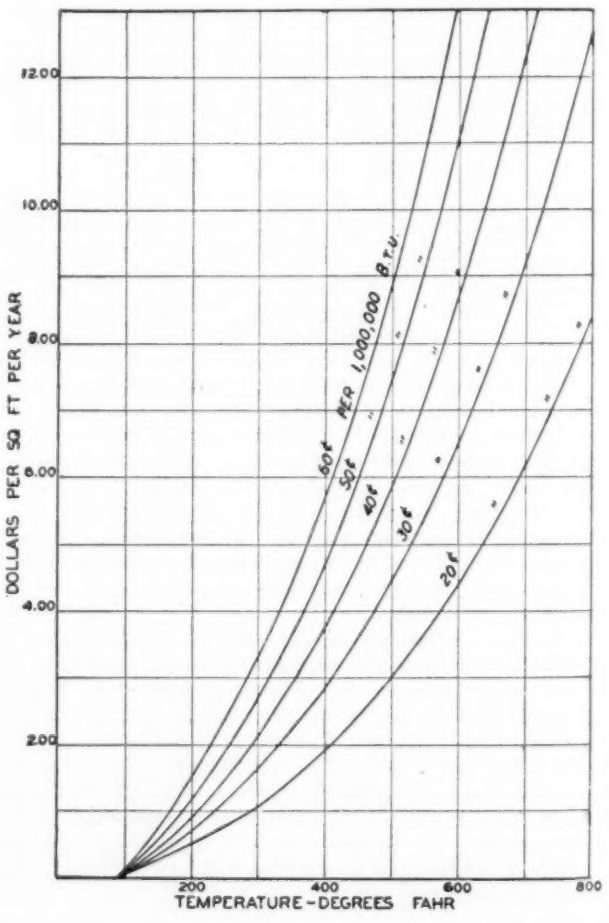

FIG. 3 ANNUAL COST OF HEAT LOSSES AT DIFFERENT VALUES OF HEAT PER 1,000,000 B.T.U.

approximately only one-fourth the value of the high-potential heat yet just as good for heating purposes. Likewise the cream of the heat from the superheated-steam lines is a somewhat expensive source of heat for preheating combustion air

Cost of Heat Losses

In spite of the fact that it does not tell the whole story, a striking picture of the cost of heat losses from bare surfaces is obtainable by reference to Fig. 3. In this chart the equivalent losses in dollars per square foot per year of 8760 hours are shown for various values of heat per 1,000,000 B.t.u. This chart serves to show more nearly the true situation than would simply figuring the fuel equivalent of the heat loss, because the curve for value of heat may be chosen so as to represent the true value and not simply the fuel cost. In selecting the curve to be used in connection with superheated steam for power generation, account should be taken of the higher value of high-potential heat as demonstrated in Fig. 1.

The dollar value of heat losses from bare surfaces may be still more forcibly illustrated by a specific example. From Fig. 3 it is readily apparent that the loss from 1 sq. ft. of bare surface, at a temperature 300 deg. fahr. above room temperature and at a value of heat of 30 cents per 1,000,000 B.t.u., is $2.60 per year. Therefore 100 sq. ft. of such surface would lose $260 worth of heat a year. If the equipment is in use 7200 hours per year instead of 8760, the loss in spite of this reduced period of operation is still 7200/8760 = $214 per year for the 100-sq. ft. area. If the surface in question is on boiler drums, headers, pipe fittings, or other apparatus where the surface temperature of the metal is nearly the same as the inside temperature, insulation which will save more than 90 per cent of this loss may be applied at a cost considerably less than one year's savings.

Even if there are only a few square feet of surface at any one point, such as on bare boiler drum heads, pipe fittings, and flanges, the total loss from a number of such small areas may be

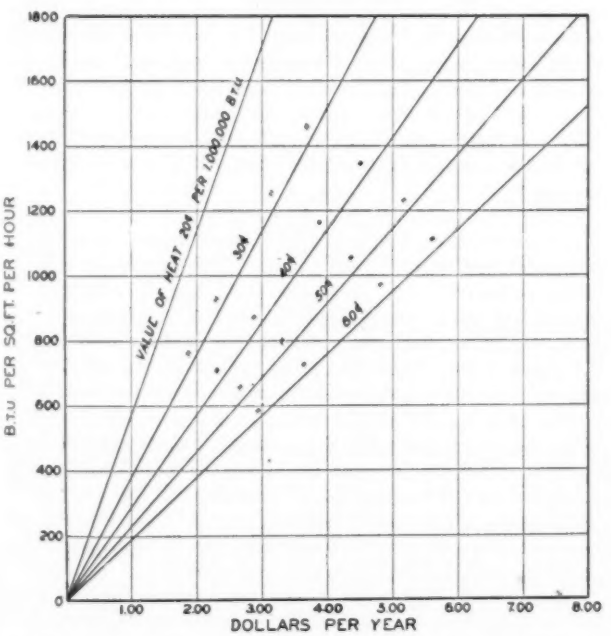

Fig. 4 Conversion Chart—B.t.u. per Hour to Dollars per Year

startlingly large. This emphasizes the desirability of minimizing the heat losses from such surfaces, which are frequently left bare even when adjacent piping is effectively insulated.

In the case of superheated-steam piping the extent of surfaces left bare is usually quite small, but, because of the higher temperatures and the greater value of the heat, the losses from such small areas may be much greater than would at first glance appear to be likely or possible. For example, the loss from one square foot of bare surface at 700 deg. fahr., and at a value of heat of 30 cents per 1,000,000 B.t.u., is $9.30 per year. If the steam pressure is 300 lb. abs., reference to Fig. 1 shows that the value of the high-potential increment of heat for power generation purposes is 1.55 times the average value. Therefore, the actual loss is $1.30 × 1.55 = $14.40 per square foot per year.

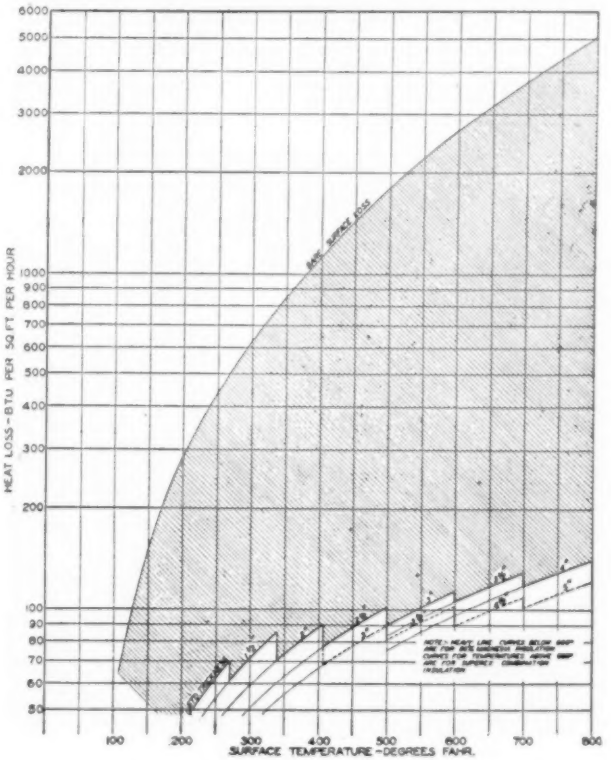

Fig. 5 Heat Losses Through Typical Insulations on 8-In. Pipe as Compared With Bare-Pipe Losses

The foregoing examples of losses and savings are based on still-air conditions. The effect of air circulation over a bare surface is to increase enormously the rate of heat loss. An air velocity of 10 miles per hour will at least double the rate of loss from such surfaces. On the other hand, the losses from insulated surfaces, where the resistance to heat flow is mostly inherent in the insulation itself, are increased but slightly in proportion by air circulation. Where the increase in heat loss from a bare surface is of the order of 100 per cent the increase in loss from a well-insulated surface, with insulation tightly applied and thoroughly sealed so that air can circulate only over its surface, is of the order of less than 10 per cent. Therefore, where surfaces are exposed to air circulation the results accomplished by insulation are proportionately much greater than those illustrated.

Where heat-loss data are available in terms of B.t.u. per hour, as in the case of Figs. 5, 7, 8, and 13 shown further along in this paper, Fig. 4 furnishes a convenient means of converting them to their equivalents in dollars per year of 8760 hours. Where the period of operation is less than the full year, values from Fig. 4 should be multiplied by the proportionate part of the year represented by the operating period.

Typical Insulation of Steam-Plant Equipment

Piping. Steam is the finished product of the boiler plant. When it leaves the superheater outlet, or the boiler nozzle if only

saturated steam is produced, it is a commodity against which all costs of production have been charged. Hence the desirability of delivering that product to the consumer with a minimum of loss en route has made the subject of pipe insulation a matter of primary interest since the early days of steam-power development.

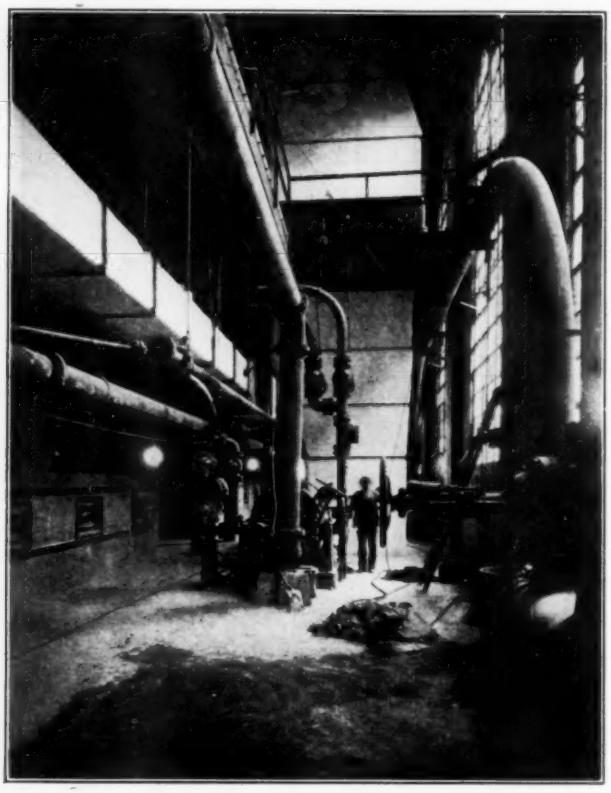

FIG. 6 INSULATED PREHEATED-AIR DUCTS, AMERICAN GAS & ELECTRIC CO., APPALACHIAN POWER CO., CABIN CREEK, W. VA.

The progressively increasing steam temperatures and the increasing costs of fuels have added still further to the relative importance of this item of power-plant equipment.

Likewise these same factors have led to the substitution of rational engineering design for the empirical methods of selection formerly used. The matter of economical thickness of insulation has been made the subject of extensive investigation, and thicknesses are now chosen with assurance that they are really economical—that they are sufficient to provide adequate reduction in heat losses and yet not so thick as to necessitate unjustified first cost. And materials have been developed which may be used with the assurance that they will provide effective results at temperatures far beyond those of present-day steam-plant practice.

But the high-pressure and high-temperature-steam mains represent only a part of the entire piping system of a modern plant. Feedwater piping, auxiliary headers, water-wall circulation piping, connections from boiler nozzles to superheaters, soot-blower piping, drip piping, etc., constitute items less important per unit of area, but when total area is considered, become of major importance in the pipe-insulation problem. Even cold-water lines must be included among the classes of piping requiring insulation if troublesome drip from condensation of moisture from the air is to be avoided.

Fig. 5 shows graphically the relative heat losses from bare and insulated pipes at various temperatures up to 800 deg. fahr. In comparing the relative positions of the curves it must be borne in mind that the vertical scale is logarithmic and that for a true comparison of ordinates the values read from the heat-loss scale must be compared. Over the greater portion of the range of the chart, the actual differences between the heat losses from bare and insulated pipes are much greater than the apparent differences between lengths of the ordinates of the respective curves.

The thicknesses of insulations represented by the heavy solid lines are typical of present-day practice in the ranges of temperature indicated and for pipe sizes $4^1/_2$ in. and larger. The heavy dotted-line curves are representative of the heat losses through the thicker insulations, which would be required for best economy at the higher temperatures by the considerations demonstrated in Fig. 1 as to the higher value of high-potential heat in superheated steam used for power generation. Both sets of thicknesses represented by the heavy-line curves are based on the same average or base value of heat, and all other conditions are the same except that the additional value of high-potential heat is not taken into account in determining the thicknesses represented by the solid-line curves. Undoubtedly, the future tendency in insulation design will be toward taking this feature more thoroughly into account.

For pipe sizes smaller than $4^1/_2$ in. the thicknesses of insulation are graduated downward as illustrated in Fig. 17. The actual procedure in the determination of economical thicknesses of insulation will be discussed more fully in connection with Fig. 17.

Preheated-Air Ducts. The preheating of the air used for combustion before admitting it to the furnace is a comparatively recent development, and, because of the fact that the heat in the air is usually recovered from what might otherwise be considered as waste heat, as, for example, the heat in the flue gases, it is often looked upon as having been obtained at little or no cost. But it does actually cost something. At least the fixed charges on the equipment required to recover the heat must be charged against it, and something more besides. But after all, *it is the value of the heat and not its cost that is important.* The major part of the cost has been expended when the equipment is put in, and that cost is incurred whether or not the heat is utilized after it is recovered.

On the other hand, the *value* depends upon the extent to which the preheated air improves the entire process of steam generation. The installation is put in not only for the purpose of imparting to the air heat which it would otherwise have to receive in the furnace, but also to improve furnace and boiler efficiency because of the higher temperatures of combustion resulting from the use of preheated air. Therefore, at the very least, the value of the preheat in the air is not less than its equivalent in fuel. Actually it must be somewhat more than that. The true measure of the value of such heat is the cost of its replacement at the point of use. Or, more specifically, its value is equal to the cost of fuel required to replace its effect—the cost of the additional fuel required to produce a given quantity of steam using air at lower temperature, over and above what would be required for the same production with air supplied at the higher temperature.

The function of insulation is, of course, to keep the heat in the air once it has been put there, and to maintain its effectiveness by minimizing temperature drop in the air from the time it leaves the preheater until it is admitted to the furnace. The heat conserved is the most valuable portion of the heat content of the air. Again the importance of maintaining temperature head and the higher value of high potential heat are very apparent.

Fig. 6, reproduced from a photograph, shows an insulated primary-air duct in the foreground and an insulated vertical connecting preheated-air duct in the background. Figs. 7 and 8 show the heat losses which may be expected from various thicknesses of typical insulating materials. Fig. 7 applies to the tem-

perature range up to 600 deg. fahr., and Fig. 8 to that from 600 to 1000 deg. fahr.

Boilers and Auxiliary Equipment. The practice in connection with the insulation of boiler drums, drum heads, other exposed portions of the boiler shell, feedwater heaters and other auxiliary equipment is so thoroughly standardized that little attention need be given it here. A notable exception to this general statement is that adequate attention has not been given to the matter of minimizing the losses of heat from the tube headers of water-tube boilers. Perhaps the reason is that they are not considered as exposed surfaces because of the doors which shut them off from view. But these steel doors offer comparatively little resistance to heat flow, and, while the losses from the headers are not as great as if the doors were not there, they are still much greater than they need be. Lining the doors with suitable insulation provides resistance to heat flow many times as great as that of the air space between the headers and the doors; because, at the temperatures involved, large air spaces are very ineffective in limiting heat flow. The heat dissipated from the tube headers is heat which has already undergone the process of being made available for steam generation. It is at the same potential, and if not lost would be of the same degree of usefulness as the heat in the saturated steam produced by the boiler. Its value is therefore just as great, and conservation at this point is a desirable step toward more economical operation.

The data on heat transmission through insulation, given in Fig. 7, for flat surfaces apply to boiler (not to boiler settings, of course) and auxiliary-equipment surfaces with a degree of accuracy sufficient for most engineering purposes, because the radii of curvature are usually quite large. If somewhat higher accuracy is required, this may be obtained by considering that the values from Fig. 7 apply to the mean area of the inner and outer surfaces of the insulation instead of to the actual area of the metal surface. If theoretical accuracy is desired, the rates of heat transfer from cylindrical and spherical surfaces of drums may be calculated by the use of the customary formulas for heat transfer through materials on such surfaces. However, such accuracy is rarely required.

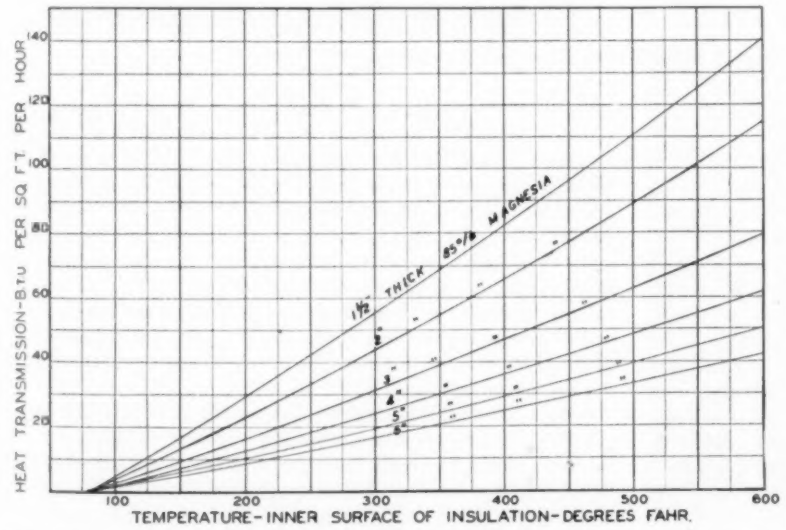

FIG. 7 HEAT TRANSMISSION THROUGH INSULATION ON FLAT SURFACES—TEMPERATURE RANGE UP TO 600 DEG. FAHR. (AIR TEMPERATURE 80 DEG. FAHR.)

Boiler Furnaces and Boiler Settings. The insulation of boiler settings and of the newer types of boiler furnaces are more recently developed fields which present many interesting problems and possibilities. In Fig. 9, typical sections of four modern types of boiler-furnace walls are illustrated diagrammatically. The sections are for the most part self-explanatory except that in Fig. 9-D the detailed arrangement of the refractories around, between, or back of the tubes is not shown. There are a number of well-known types of water-cooled walls differing considerably in design, but so far as insulation is concerned the general principles governing its application are closely similar in practically all cases. First, the walls provide, in addition to the water tubes,

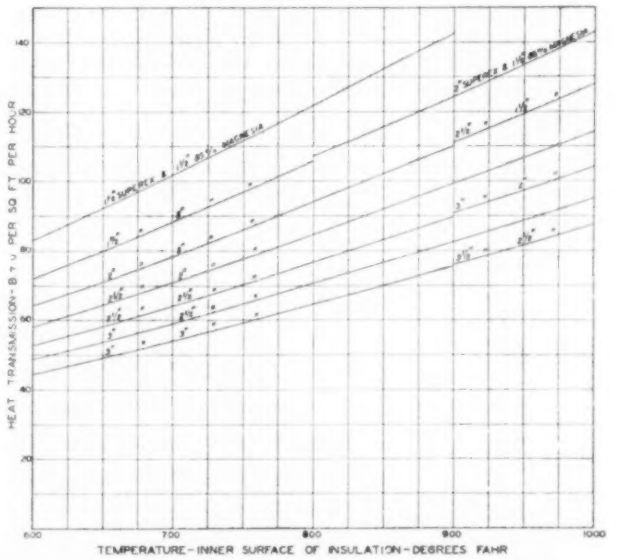

FIG. 8 HEAT TRANSMISSION THROUGH INSULATION ON FLAT SURFACES—TEMPERATURE RANGE 600 TO 1000 DEG. FAHR. (AIR TEMPERATURE 80 DEG. FAHR.)

some arrangement of refractories (cast iron would be considered a refractory in this sense) which protects the insulation from being subjected to the excessive temperatures that would penetrate between the tubes if such provision were not made. Then there is the insulation itself, and finally an outside protective and air-sealing finish for the insulation, which consists of asbestos wood, steel plate, or hard-finish insulating cement. Fig. 10 illustrates a typical insulated water-cooled wall on which the protective finish for the insulation consists of asbestos-wood panels with steel battens gasketed to provide air-tightness.

An installation of the type of wall represented by Fig. 9-A is illustrated in Fig. 11. The insulation is applied against the outside of a solid firebrick wall, and the protective and air-sealing finish consists of asbestos-wood panels over the greater part of the area. On the extreme upper portions, however, hard-finish insulating cement provides the protective finish and the air-sealing medium.

The veneer wall construction illustrated in Fig. 9-B is often used in connection with the insulation of existing boiler settings as well as on new work. In this case, however, the bonding courses shown in the diagram are not used and the veneer course is secured to the existing wall by means of metal fastenings. In such cases a hard-finish insulating cement is usually applied over mesh-wire reinforcement to cover the metal fastenings and

provide a suitable finish. For new walls, where the bonding courses may be used, types of insulating brick are available which provide a durable and attractive finish without the use of other means of finishing.

There are a number of designs of air-cooled walls; therefore Fig. 9-C is simply diagrammatic of the principles involved; and no attempt is made to show details of wall construction. However, in the main these walls consist of an inner refractory wall, a space or spaces for the circulating air, and an outer insulating casing. In general, the principles already discussed under preheated-air ducts, in connection with the value of retaining the heat in preheated air, apply also to air-cooled boiler-furnace walls. In Fig. 12 is illustrated an air-cooled wall in the course of construction, and the application of the insulation to the inside of the casing is clearly shown.

There is still another type of insulated construction, not illustrated in Fig. 9, which is used with good results in the settings of smaller boilers of capacities up to 500 hp. This is the so-called "core-wall" type, where a course of insulating brick is used between a firebrick lining on the furnace side and a course of common brick on the outer side of the wall.

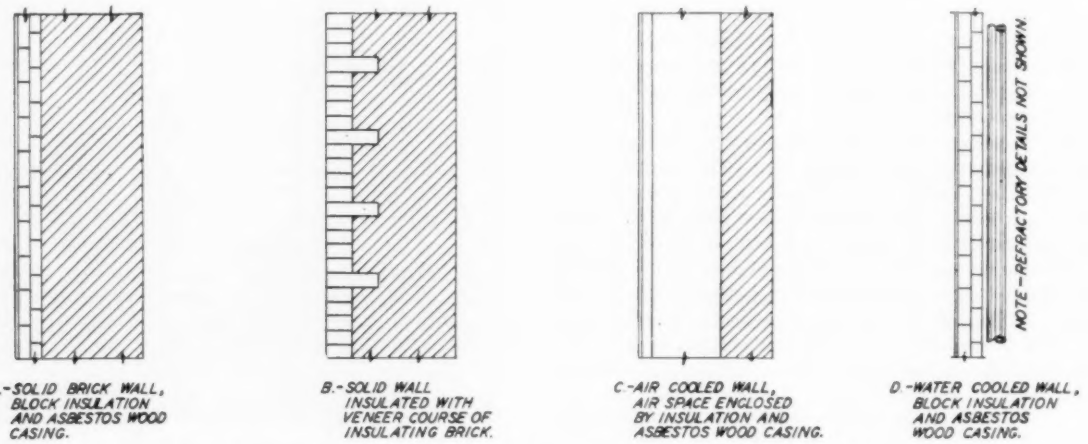

FIG. 9 TYPICAL SECTIONS OF FOUR MODERN TYPES OF BOILER-FURNACE WALLS

Results Accomplished by Insulation on Boiler Furnaces. The relative heat losses from solid refractory walls with and without insulation are shown in Fig. 13. The savings represented by the differences between the curves for insulated and uninsulated walls are very conservative since the conductivities of firebrick used in the computations were purposely taken in the low rather than the high portion of the range of firebrick conductivities. The values used range from 6.0 B.t.u. per square foot per degree temperature difference per inch of thickness per hour at a mean temperature of 1000 deg. fahr., to 8.77 B.t.u. at 2600 deg. fahr. mean temperature. Many investigators have shown conductivities at least 25 per cent higher than these, and higher conductivities of the firebrick would result in higher losses from uninsulated wall than those shown in Fig. 13. The losses through insulated walls would be increased somewhat by such higher firebrick conductivities, but to a much smaller extent; therefore, under such conditions the savings would be greater than those shown. Where insulating brick is used the thickness is usually $4^1/_2$ in., and the losses through walls insulated in this manner are closely approximated by the curve for 4-in. thick block insulation.

Insulation may be applied in such manner as to minimize air infiltration as well as heat-transmission losses. Because of wide variations in their magnitudes on settings without insulation, it is not possible to evaluate as definitely the extent of air infiltration losses, but frequently the savings effected by insulation in reducing these losses is at least as great as those due to its effect in minimizing heat-transmission losses.

On both air-cooled walls and water walls the savings by insulation are proportionately much greater than on solid refractory walls, and a given thickness of insulation applied to either of these types of walls will bring the total loss down to a point far below what it would be if the same amount of insulation were applied on a solid refractory wall. This is due to the fact that the portion of the heat flow stopped by the insulation is immediately picked up and carried away by the cooling medium, instead of tending to increase the temperature head back of the insulation as it does on refractory walls. The fact that the losses from cooled walls can be reduced by insulation to a very low point is most fortunate, because, with the greatly increased wall areas that accompany the larger furnace volumes now used, if the heat transmission per unit area could not be made small, the resulting total losses would become a serious factor in limiting economy.

Breechings, Flues, and Stacks. Where there are no air preheaters or other means for utilizing the heat in the gases, the principal reason for insulating breechings and flues is to prevent excessive heating of the boiler room. There is also a corollary advantage, however, in the improvement of draft due to the minimizing of temperature drop in the gases before they reach the stack. Also, insulation is often placed inside of the breeching in order to provide a protective lining to guard the steel from corrosion. In many cases, such as that illustrated in Fig. 14, the insulation is used to serve the double purpose of protecting the steel and of conserving the heat content of the gases for utilization at some other point, as, for example, in an industrial process requiring the use of such heat.

Where there are economizers or air preheaters or both, there are still greater advantages resulting from the insulation of uptakes and flues. In such cases the heat saved has a real dollar value, and the maintenance of temperature head increases the effectiveness of heat recovery in the economizer or air preheater. While the ducts or breechings carrying the spent gases from the recovery apparatus to the stack are at lower temperatures, and the value of the heat saved is a much smaller item, the very fact that they are at lower temperatures increases the tendency toward corrosion due to condensation of moisture on the steel and increases the importance of insulating for the purpose of minimizing corrosion troubles.

Steel stacks are often provided with insulating linings for the purpose of protecting the steel from such corrosive action. Of

course, in the case of stacks located in buildings there is a further very important requirement for insulation in order that overheating of spaces adjacent to the stacks may be avoided. The stack shown in Fig. 16 happens to be an industrial installation, but it was chosen as an illustration because, being a close-up, it shows clearly the method of insulating, and the same method is widely used for the insulation of boiler-plant stacks.

Economical Thickness of Insulation

When the decision has been reached that a given equipment should be insulated, the solution is not yet complete. The question remains as to how effectively it is to be insulated. Among the factors to be considered are, of course, the adaptability of the material to the conditions of temperature and usage to which it will be subjected, its durability, and the relative permanence with which it retains its initial insulating value. However, with these questions decided, there still remains the question as to what thickness would be most effective. Obviously, the greater the thickness the lower will be the heat loss, but as thickness is increased, fixed charges are also increased; therefore, the

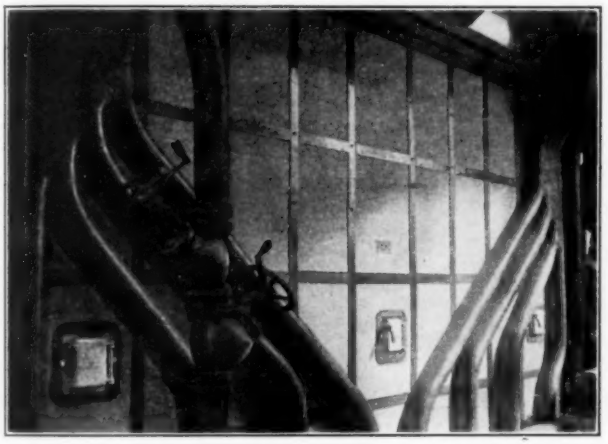

Fig. 10 Insulated Water-Cooled Wall, Virginia Electric & Power Co., Norfolk, Va.

thickness at which the sum of these two costs is a minimum is that which is most economical. At this point all of the insulation pays a satisfactory return on the investment represented by its cost. This is true even of the last increment of thickness, whereas the insulation as a whole may pay a return many times the required minimum.

Return on the investment *properly interpreted* is of course a most important consideration, but, as is true in connection with any percentage item, correct interpretation is most essential. The frequent misinterpretation of the significance of such terms as "return on investment" and "years required to repay first cost" is by no means confined to insulation. In the case of any equipment, the one which pays the highest *per cent* return on the investment, or which repays its first cost in the shortest length of time, is not by any means necessarily the most economical for the purpose. It is more likely to be the least economical. Nor is this the paradox which at first sight it might appear to be. The very fact that an equipment pays an exceptionally high rate of return on its cost, several hundred per cent, for example, is a very good indication that there may be, and most likely is, an opportunity to make still further investments at rates of return which, while not as high as in the first instance, are still highly attractive.

All of this is so very elementary that further discussion should hardly be necessary, but because of the frequent misinterpretation of the principles involved, not only in the case of insulation but also in connection with other equipment affecting operating economy, a typical example is given which will serve to illustrate these principles still more clearly. It will be noted from Table 1 that the percentage returns on the investments are all very high, but it will be noted further that as the thickness is increased the percentages are decreased. Likewise, as thickness is increased

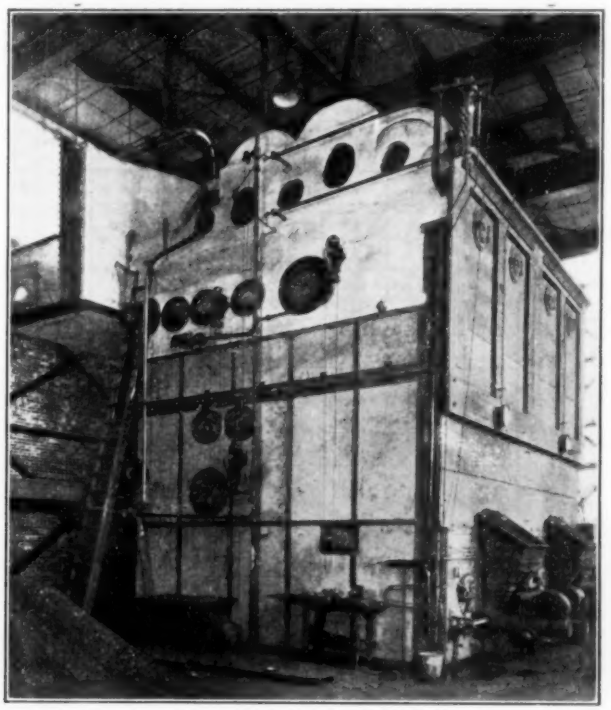

Fig. 11 Insulated Boiler Setting With Solid Refractory Walls, Worthington Pump & Machinery Co., Buffalo, N. Y.

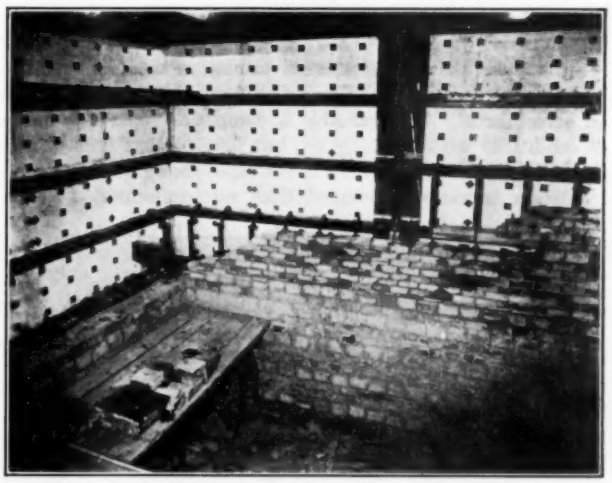

Fig. 12 Application of Insulation in Air-Cooled Wall, Worcester Salt Co., Silver Springs, N. Y.

the length of time required to repay first cost is increased. Therefore, if the trends in either of these items could be considered as a deciding factor, even 1-in. thickness would be too great since the trends indicate increasing percentage returns as the thickness approaches zero.

Yet a return of 1000 or 1200 per cent is not bad, so something

TABLE 1 PER CENT RETURN ON INVESTMENT AND TIME REQUIRED TO REPAY FIRST COST

[Based on a loss from bare, flat surface of 1600 B.t.u. per sq. ft. per hour (corresponding approximately to the loss at a temperature difference of 400 deg. fahr.) and value of heat at $0.50 per 1,000,000 B.t.u. Insulation is provided with 1/2-in.-thick asbestos-cement finish in addition to thickness shown. Also the block insulation is applied in two layers where thickness is 3 in. or more. These items account for the non-proportionality of cost to thickness.]

Thickness of insulation, in.	Annual loss per 100 sq. ft.	Annual saving	First cost of insulation	Per cent annual return (gross)	Years to repay first cost
0	$701.0	...	...	...	...
1	65.0	$636	$ 50	1272	0.08
2	38.0	663	65	1020	0.10
3	27.0	674	85	793	0.13
4	21.0	680	100	680	0.15
5	17.0	684	115	595	0.17
6	14.5	686.5	130	528	0.19

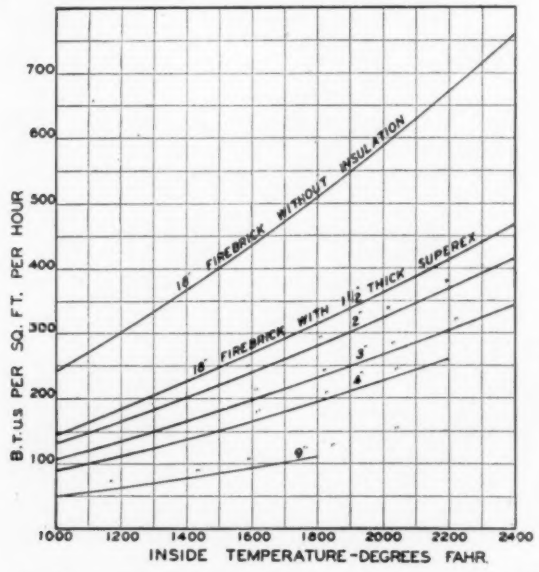

FIG. 13 HEAT TRANSMISSION THROUGH INSULATED AND UNINSULATED FURNACE WALLS—18-IN. FIREBRICK (AIR TEMPERATURE, 80 DEG. FAHR.)

is evidently wrong with that method of comparison. Such returns show that at least some insulation must be justified. This illustrates clearly the limit of usefulness of the term "return on investment." It is valuable in comparing separately *one set* of conditions with *one other set*, but beyond that it is of little further use. Thus, this item in the table shows that 1-in.-thick insulation is more economical than no insulation. Likewise,

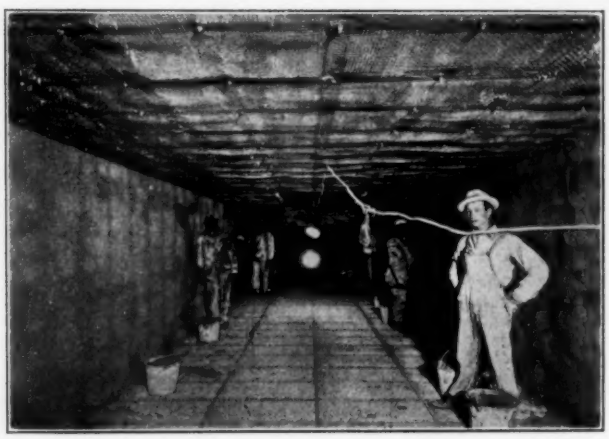

FIG. 14 TYPICAL FLUE-LINING INSULATION, FORD MOTOR CO., IRON MOUNTAIN, MICH.

it shows that 6-in. insulation and each of the other thicknesses shown is better than none at all, but it does not show that 6-in. is more economical than 1-in. or vice versa. To determine which of the insulations is the better suited to the conditions they must be compared with each other. This is done in Table 2,

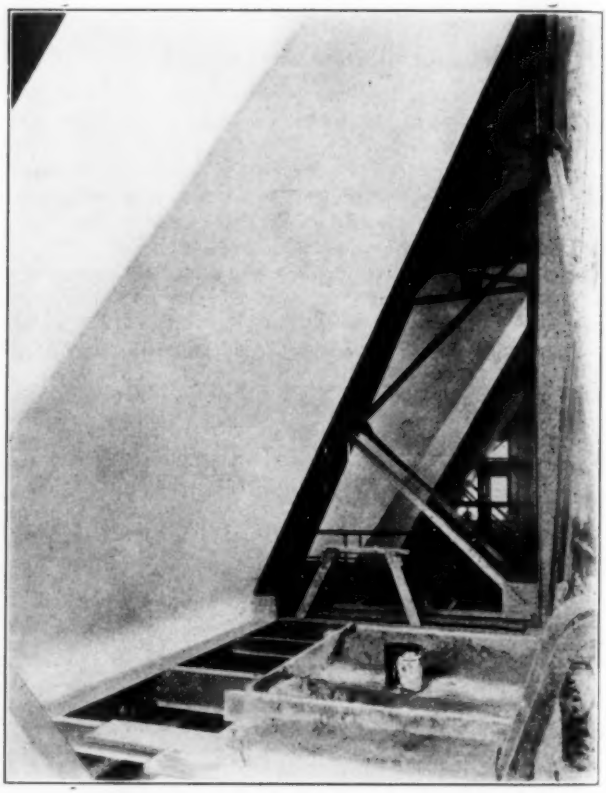

FIG. 15 TYPICAL EXTERNALLY INSULATED FLUE, CONNECTICUT LIGHT & POWER CO., DEVON STATION

FIG. 16 TYPICAL STACK-LINING INSTALLATION, ILLINOIS PACIFIC GLASS CO., LOS ANGELES, CALIF.

and it is at once apparent that 2 in. thick is more economical than 1 in. thick since the *additional* saving pays a return of 180 per cent on the *additional* cost. Likewise, 3 in. thick is preferable to 2 in., but by a decreased margin, and so on down to the point

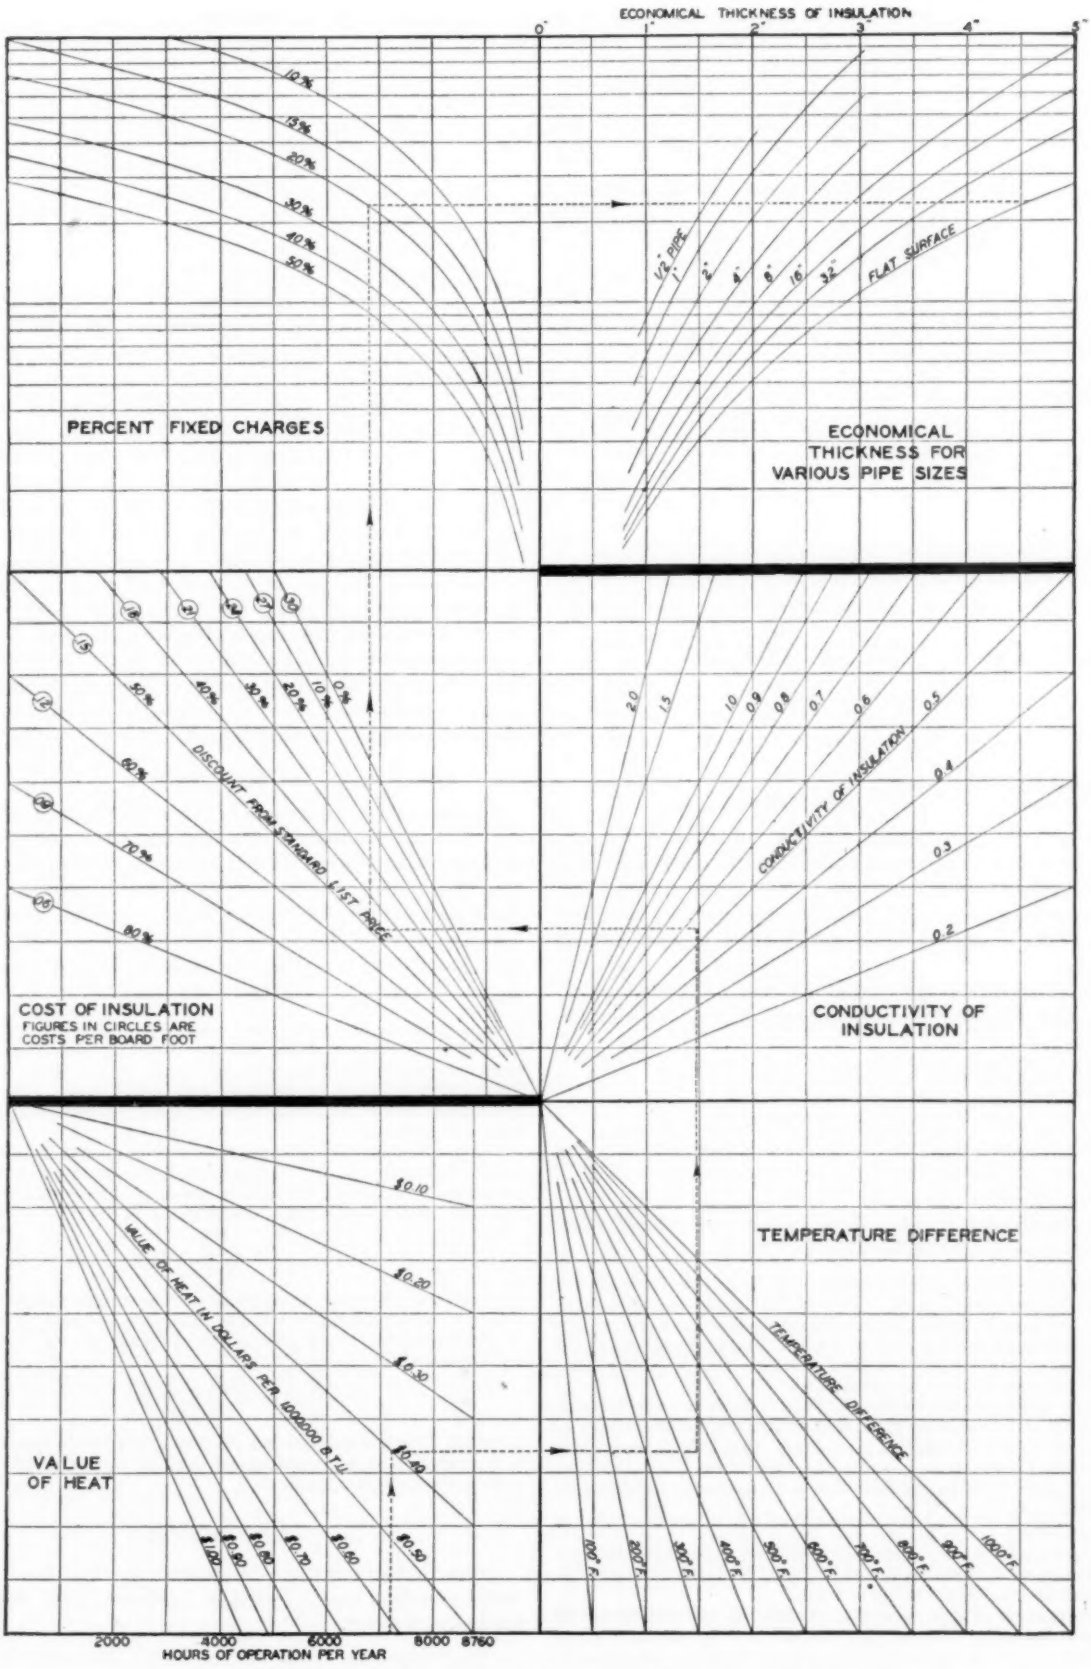

FIG. 17 CHART FOR DETERMINING ECONOMICAL THICKNESS OF INSULATION

where the additional saving by added thickness no longer pays the required minimum return on the additional cost. In this example, if such minimum acceptable return is 20 per cent, the most economical thickness is 5 in., since the additional saving by 6-in.-thick insulation fails to pay the required return on the additional cost, whereas the *last inch* of the 5-in. thickness pays 27 per cent on its cost.

But there is a far more direct and convenient method of determining the economical thickness. This is based simply upon determining the total cost, heat loss per year plus cost of insulation per year (first cost times per cent annual fixed charges), and choosing the thickness at which the sum of these two items is the lowest. This method is illustrated in Table 3, which is based on the same example as that employed in Tables 1 and 2.

TABLE 2 PER CENT RETURN ON ADDITIONAL INVESTMENT REPRESENTED BY EACH INCH OF ADDITIONAL THICKNESS

Thickness of insulation, in.	Annual loss per 100 sq. ft.	Annual saving by additional 1 in. thickness	First cost of insulation	Cost of 1 in. additional thickness	Per cent return on additional investment
1	$65.0	..	$50	..	..
2	38.0	$27.0	65	$15	180
3	27.0	11.0	85	20	55
4	21.0	6.0	100	15	40

6	14.5	130	26	40.5

[1] Annual fixed charges = 20 per cent.
[2] The most economical thickness for the stated conditions is 5 in.

In an earlier paper [Trans. A.S.M.E., vol. 48 (1926), pp. 1269–1318] the author presented a rational method of determining economical thicknesses of insulation. The chart Fig. 17 is based upon the equations developed in that paper, but it has been simplified in such a manner that the entire solution may be obtained graphically.

The principal factors involved in determining the economical thickness and the order in which they are taken into account are as follows:

1 Hours of Operation per Year
(8760 hours for continuous operation)
2 Value of Heat in Dollars per 1,000,000 B.t.u.
(Not necessarily the average cost of heat, but its value at the given potential. See Fig. 1)
3 Temperature Difference
(Temperature inside of equipment to be insulated minus temperature of surrounding air[2])
4 Conductivity of Insulation
(B.t.u. per square foot per degree temperature difference per 1 in. thick per hour)
5 Cost of Insulation, per cent discount from standard list
(Curves are also marked with respective costs per square foot 1 in. thick to provide for materials whose costs are not figured in terms of discount from standard list)
6 Per Cent Annual Fixed Charges
(Usually about 15 per cent in the classes of work under discussion)
7 Shape of Surface or Pipe Size
(Curves are given for cylindrical surfaces of various diameters and a curve is also shown for flat surfaces.)

In order to use the chart, start at the lower left-hand corner and proceed to the right to a point representing the given number of *hours of operation per year;* then proceed vertically to the line representing the given *value of heat;* thence horizontally, to the right, to the line representing the given *temperature difference;* thence vertically to the line representing the *conductivity* of the given material; thence horizontally, to the left, to the line representing the given *discount* on that material (or given cost per square foot, board measure); thence vertically to the curve representing the required *per cent annual fixed charges;* thence horizontally, to the right, to the curve representing the given *shape;* thence vertically to the scale at the top of the sheet, where the *economical thickness* may be read off directly. The dotted line on the chart illustrates its use in solving a typical example. The actual thickness used will, of course, be the available commercial thickness nearest to the thickness as read from the chart.

Conclusions

No attempt has been made in this paper to present a lengthy discussion of insulation details. The central thought has been to set forth as clearly as possible the principles involved, and to present the subject in its true perspective. Especial emphasis has been given to the importance of maintaining temperature head and to the higher value of high-potential heat. To whatever extent these principles have been made more clear, to that same extent the effort has been worth while.

[2] Where there is but little resistance to heat flow between the surface to be insulated and the source of heat, as in the case where the source of heat is steam, water, or rapidly moving gases on one side of a thin metal plate or pipe wall and insulation is to be applied directly to such surface, the resulting thickness read from the chart is at once the correct economical thickness.

However, it must be borne in mind that, if there is a considerable resistance to heat flow other than that offered by the insulation itself, as in the case of insulation on a brick furnace wall, correction must be made for the effect of such other resistances. For example, if the insulation is to be applied to a wall having a resistance of $2.0 \left(\frac{\text{thickness}}{\text{conductivity}} = 2.0\right)$ and the conductivity of the insulation is 0.6 B.t.u. per sq. ft. per deg. temperature difference per 1 in. thick per hour, the correction which must be subtracted from the thickness obtained from the chart is $2.0 \times 0.6 = 1.2$ in.

The explanation of this correction is that the rational equations upon which the chart is based give the thickness of insulating material which would be required if there were no insulating value in the construction other than that offered by such material itself. If other resistances to heat flow are already present, naturally less additional insulating value will be required, and the correction simply involves deducting the thickness of insulation equivalent in insulating value to the resistances already present. (In the chart as plotted, deduction of 0.3 in. has already been made for outside surface resistance.)

For flat surfaces, the rational equation for economical thickness is quite simple; therefore, for furnace walls and other cases where temperatures involved are beyond the range of the chart, the following equation for flat surfaces may conveniently be used:

$$x = \sqrt{\frac{ak}{b}} - Rk$$

in which x is the most economical thickness, k is the conductivity, b is the cost of insulation *per inch thickness per year*, R is the sum of the resistances of all *other* elements in the construction, including surface resistance, and

$$a = \frac{Y(t_0 - t_a)M}{1{,}000{,}000}$$

in which Y is hours operation per year, t_0 is inside temperature, t_a is temperature of surrounding air, and M is the value of heat in dollars per 1,000,000 B.t.u.

Discussion

Irvin G. McChesney.[3] A glimpse of actual conditions met with by users of pipe covering is of interest in the discussion of the author's paper.

To guide purchasing policy it is necessary to compute economic thickness and minimum cost of coverings having suitable physical characteristics.

In a problem concerning a large heat-distribution system, testing and computations were carried out as described by the author in the 1926 Transactions.

A brief summary of data used in computations is given in Table 4.

For brevity only the results of extreme service conditions are considered; high pressure overhead and low pressure underground.

Bare pipe not considered, there remains the problem of balancing one brand of covering against another on minimum cost.

The author's chart will serve for approximation of economic

thickness in many cases, but fails to give minimum cost, which is the criterion of brand selection, where physical properties are satisfactory.

As the author brought out in oral discussion the nature of the minimum point is important.

Figs. 18 and 19 demonstrate the nature of minimum points.

Fig. 18 represents a covering of low conductivity and high fixed charges, and Fig. 19 relatively high conductivity and low fixed charges.

The author's consideration of high potential heat adds an important variable to power plant pipe covering design.

EDGE TAYLOR COPE.[4] It is interesting to note the development which has occurred in the design of steam-pipe covering in the past five years. Mr. McMillan is to be congratulated on bringing together and expressing in such a clear manner the essential facts in the matter of determining economical thickness of steam-pipe covering.

Fig. 17 is especially good in that it takes into consideration all the factors entering into the determination of economical thickness of steam-pipe covering. The writer has checked the values of covering thickness as obtained by the use of this chart against the values of thickness in use at Trenton Channel Plant and finds the two sets of values in substantial agreement over the whole range of steam temperatures and pipe sizes. The covering thicknesses for Trenton Channel Plant were calculated according to the procedure outlined in a paper presented by Mr. W. A. Carter and the writer in 1925, at the Milwaukee meeting of the Society.[5]

Since Trenton Channel Plant was one of the early ones in which compound covering on steam pipes was used, it was thought worth while to check up the temperature of covering as it operated against the temperatures as calculated. A section of 16-in. main steam piping near one of the 50,000-kw. units was selected for a temperature test. Calibrated iron-constantan thermocouples were used to read temperatures. The arrangement is shown in Fig. 20. At a later date a similar test was made on a 12-in. superheated steam line in the same plant. The readings are as follows:

Nominal pipe size, in.	12	16
Total thickness of covering, in.	4	3⅝
Thickness of inner layer (high-temperature-resisting), in.	1⅛	2
Thickness of outer layer (85% magnesia), in.	2	2
Temperature of outside of pipe, deg. fahr.	698	700
Temperature at outer surface of inner layer of covering, deg. fahr.	422	450
Temperature at outside of covering, deg. fahr.	133	124
Calculated temperature at outside of covering, deg. fahr.	126	121

It is to be noted that there is some difference between the actual and the calculated temperatures of the outside surface of the covering in each case. This can be accounted for in part by the fact that it was not possible to buy covering of standard thickness that exactly agreed with the thicknesses shown by the design. A thickness of inner layer (high-temperature-resisting covering) greater than that shown by the design was selected in each case. This covering is not quite so good an insulator (a better heat conductor) as 85 per cent magnesia. The result was that the total covering thickness was made up of a greater portion of the poorer insulator than was shown by the design. The heat conduction of the covering is a little greater than was hoped for, and the outside temperature is a little higher than the design called for.

It is worth noting, however, that the values of mean absolute thermal conductivity were used as supplied by the manufacturers of the various covering materials. The writer is of the opinion that the results obtained at Trenton Channel are excellent evidence of the accuracy of the values given and of the uniformity of the material supplied at different times. The 16-in. pipe was installed and tested in 1924, and the 12-in. pipe was installed in 1927 and tested in 1928.

There is another item which the writer would like to note in regard to this matter of pipe covering. Many engineers have an exaggerated idea of the loss resulting from poor insulation under modern conditions in large plants. Let it be understood that this is no effort to belittle the importance or value of adequate covering for steam piping, because the writer believes in it thoroughly. We ought, however, to keep a proper perspective. Let us take a concrete case and make a few calculations. Let us assume a 16-in. pipe carrying superheated steam at, say, 700 deg. fahr. and passing 400,000 lb. of steam per hour. Let us suppose that this pipe is bare and in air maintained at 80 deg. fahr. This last assumption probably would be true at the start of our imaginary conditions, but would not last for very long because of the loss of heat from the pipe. This would be the worst condition, so let us assume that it could happen.

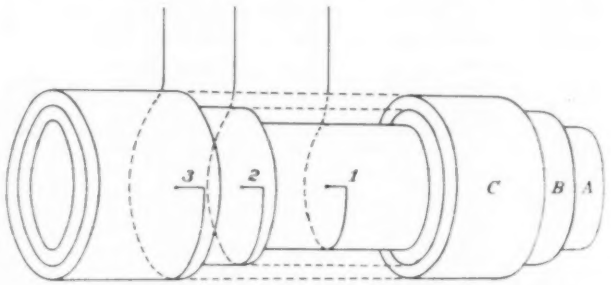

FIG. 20 ARRANGEMENT FOR MEASURING THE TEMPERATURE OF PIPE AND OF COVERING

(*A*, pipe; *B*, high-temperature-resisting layer; *C*, 85 per cent magnesia layer. Position of thermocouples: 1, hot junction peened into shallow drill hole in pipe; 2, hot junction laid between 85 per cent magnesia and high temperature-resisting layers; 3, hot junction between 85 per cent magnesia layer and canvas covering.)

Taking the value of heat loss from this bare pipe from Heilman's tests[6] and taking the temperature of the pipe equal to the steam temperature (the worst condition, not quite, but nearly true), the loss per 100 ft. of bare 16-in. pipe would be about 1,400,000 B.t.u. per hr. Now, 400,000 lb. of steam are passing this 100 ft. of pipe each hour. The average loss per pound of steam, therefore, would be about 3.7 B.t.u. This would account for a loss of temperature of the steam of approximately 7½ deg. fahr. The manufacturer tells us that a drop of 11 deg. fahr. in superheat temperature will produce an increase of 1 per cent in the turbine-water rate. We must conclude that the worst condition, while undesirable, is not really a tragedy.

Now let us consider the insulated 16-in. pipe which the writer tested at Trenton Channel. The outside temperature was 133 deg. fahr., and the outside diameter was 24 in. (4 in. of covering). At the best loading of the 50,000-kw. turbine served by this 16-in. pipe there were about 400,000 lb. of steam passing per hour. Let us calculate the loss of heat from this pipe by using Heilman's formula for the loss of heat from canvas-covered surfaces.

$$h = \frac{147.6\, D^{0.81}(tc - ta)}{272.5 - (tc - ta)}$$

[4] Detroit Edison Co., Detroit, Mich. Assoc-Mem. A.S.M.E.

[5] "The Rational Design of Pipe Covering for Pipes Carrying Steam up to 800° F." W. A. Carter and E. T. Cope. Trans. A.S.M.E., vol. 47, 1925, p. 255.

[6] "Heat Loss From Bare and Covered Wrought-Iron Pipe at Temperaturesup to 800 Deg. Fahr." R. H. Heilman, Trans. A.S.M.E., vol. 44, 1922, p. 301.

where h = B.t.u. lost per linear foot of pipe per hour.
D = outside temperature of covering in deg. fahr.
tc and ta = temperature of the surface of the covering and of the air, respectively, in deg. fahr.

The loss from 100 ft. of pipe would be about 46,800 B.t.u. per hr.

The loss per pound of steam passing would be 46,800 ÷ 400,000, which equals 0.117 B.t.u. The loss of temperature would be about 0.24 deg. Obviously the increase in turbine-water rate because of such a small temperature loss would be negligible.

The economical thickness of covering must be that thickness which saves enough coal annually to balance the allowed annual fixed charge on the cost of the covering installed.

E. F. MUELLER.[7] The presentation in the paper of the question of economic thickness of insulation is in such a simple and usable form that it seems desirable to carry the argument somewhat further and to state the conclusion in a different form. The paper suggests the conclusion that the thickness of insulation corresponding to the minimum total annual cost is the most desirable.

The characteristics of a maximum or minimum may be, however, as important as or more important than the fact that such a maximum or minimum exists. Not all maxima and minima are alike. A maximum may be as sharp as the point of a needle or as broad and flat as the top of a table, and the use to be made of our knowledge as to the existence of the maximum may be decidedly different in the two cases.

The arithmetical, graphical, or analytical processes used in determining a minimum can do no more than give the logical result of the assumptions originally put into the analysis. Yet it seems to be a well-developed trait of human nature, once the existence of a maximum or minimum has been established by analysis, to consider such a maximum or minimum as an optimum to be sought at any cost for its own sake, without regard to the nature of the maximum or to other factors not included in the analysis. This tendency appears to be the more pronounced when the demonstration is not completely understood. It is unfortunately more common in research than in engineering work and occasionally leads to much loss of time and effort.

When a maximum or minimum having desirable characteristics has been found, it is important, therefore, not to stop with this discovery, but to examine the values on either side. If the maximum is sharply defined, it may be well to attempt to attain it, but if it is found to be very broad, so that essentially the same value as the maximum is found over a wide range, a value considerably removed from the maximum indicated by the analysis may be dictated by other considerations.

The proposition just stated is of very general applicability, and the data of Table 3 of the paper are merely an excellent illustration. The conclusion from Table 3 and the discussion leading up to it might be stated as follows:

"If only one kind of insulation is to be used, and if the costs of heat loss and of insulation are those given in the table, then, for fixed charges of 20 per cent, the 5-in. thickness is the most economical."

However, an examination of the very small differences between the estimated total costs of 4-in., 5-in., and 6-in. thicknesses shows that even such a highly restricted conclusion is hardly warranted by the data, but that we may conclude:

"As far as total annual costs can be estimated in this case, the 4-in., 5-in., and 6-in. thicknesses are equally economical, and the choice between them may be based on other considerations."

[7] Physicist, Bureau of Standards, Washington, D. C.

Furthermore, considering the inherent uncertainties in estimated costs and that the maximum may be very appreciably displaced by comparatively small changes in the initial assumptions, a feature which it may prove profitable to examine more in detail, it seems that we may conclude that considerations of total annual costs allow a choice between thickness from 3 to perhaps 8 in., and within this range the choice may be dictated by considerations other than total annual costs. Such other considerations will doubtless present themselves in embarrassing abundance to any one charged with designing a modern steam-generating plant. By way of illustration, such factors as the probable period of usefulness of the plant, the use of two or three thicknesses only instead of a large number in the whole plant, the trend in fuel costs, the stability of the industries served by the plant, the availability of capital, could well be taken into account in choosing between the several equally economical thicknesses indicated by the analysis of total annual costs.

The gist of this discussion is given in the statement that an analysis based on total annual costs gives not the most economical thickness but a range of thicknesses, all about equally economical, from which a choice may be made.

HERBERT B. REYNOLDS.[8] The author has called attention to a very important point which should be considered in providing for heat insulation, and that is the fact that high-potential heat of steam is more valuable than the average heat value. In fact, I think it actually has a higher value than the curves in Fig. 1 would indicate.

In order to demonstrate the relative value of high-potential heat and the average value in a practical case, I have studied the heat losses which would occur from 200 ft. of bare 18-in. steam line or its equivalent between boilers and a 35,000-kw. turbine. A pressure of 300 lb. abs. and a superheat of 200 deg. fahr. at the boilers were assumed, while the average steam flow was taken at 250,000 lb. per hr. Using the data for bare-pipe losses as given in Fig. 5, it was found that the actual loss of heat due to radiation would amount to 0.83 per cent of the total heat passing through the line. However, this heat loss would cause a reduction in the superheat at the turbine throttle of 21.4 deg. fahr., which in turn would cause an increase in the steam consumption of the turbine of 2.14 per cent, allowing 1 per cent increase for each 10 deg. decrease of superheat. It will thus be seen that the ratio of the value of high-potential heat to average value is 2.14 ÷ 0.83, or 2.58, while Fig. 1 gives this ratio as 1.45 for the pressure and temperature assumed. This higher value of the high-potential heat of course does not exist during the time when steam lines are under pressure but with no flow of steam through them.

P. NICHOLLS.[9] The outstanding urge advanced by the author is that insulation should be bought on the basis of the computed economical thickness, and that figures cannot lie. There is no question of the principle of the economic thickness being correct and that one can consider its predictions as final. Instead of questioning its principles it is the function of the engineer to examine the numerical values used for the various factors included in the general equation by which the economic thickness is determined. Some are definite and others are based on the future and involve probability, and this is where the engineer can use his good judgment.

The initial cost is fixed, and so in all probability is the temperature difference; past experience indicates that in some

[8] Mechanical Engineer, Interborough Rapid Transit Co., New York, N. Y. Mem. A.S.M.E.

[9] Supervising Engineer, Fuels Section, Pittsburgh Experiment Station. U. S. Bureau of Mines.

types of plants steam pressures or the superheat may be increased which would warrant the use of a thicker insulation. One probably tends, however, to assign too high a temperature difference to furnace and other walls, and takes maximum instead of average of time and the area conditions. The initial conductivity of the insulation is known, and, in general, insulation materials used on hot surfaces do not increase their inherent conductivity; on the other hand, all other probabilities will tend to give loss of insulation value, such possible causes being poor workmanship, mechanical damage or failure, cracks, and air infiltration.

The value of the heat used should be the average during the life of the insulation, which is looking into the future; although we generally think of the cost of fuel as increasing, yet past experience indicates that improvements in operation or other means have decreased the unit cost; each type of plant will require special consideration to predict the future probability.

Fixing the value to be used for the per cent fixed charges involves the most guessing; the insulation salesman will be optimistic and make it low, whereas most of the probabilities will tend to increase it. Repairs or changes in the construction insulated, shutdowns, and obsolescence cause increase, and different values should be used for furnaces than for steam pipes, for example.

Finally, there is the general decision as to whether one would prefer to have the money now or to invest it for the future.

The chart developed by the author is a time saver, but it could well have included the factor of percentage of time the insulation is in service. There should also be an accompanying sheet with concise tabulated guidance for selecting values for the various factors in relation to types of plant and apparatus insulated, for the translation of pipe insulation to board feet, and other data which sales experience has shown to be useful.

The paragraph on air-cooled and water walls probably tends to give the credit for savings to the insulation instead of to the wall construction. Naturally a given thickness of insulation will give a lower heat loss than it would if used on a refractory wall, but that is why the money is put into the air or water construction, and the one that would be expected to save on the cost of insulation.

F. L. Wagner.[10] No mention has been made in this paper of the cost of applying covering in various thicknesses. This cost of application will vary tremendously with the nature of the lines and equipment to be covered, their location, accessibility, and several other factors.

The writer feels that this application cost should be duly considered in selecting the economical thickness of insulation for any given set of lines or equipment.

This labor cost can readily be included with the material cost, as shown on Fig. 17, by taking the discount from standard list price of the insulation applied, instead of the discount from list price of the insulation itself.

Studies of Moisture at High Rates of Evaporation

By A. R. MUMFORD,[1] NEW YORK, N. Y.

In this paper the author gives particulars of studies made in an attempt to reduce or eliminate the moisture in steam from boilers operated at the high evaporative rate of 25 lb. per sq. ft. of boiler and furnace surface, using 90 per cent make-up and full chemical treatment in the boiler for scale elimination. From these studies he concludes that:

1 The concentration of the hydroxyl radical is a factor in the production of wet steam which acts independently of the rate of evaporation, or of the concentration of other solid or dissolved chemical substances, and which has a critical value varying with the boiler design.

2 The production of dry steam at high rates of evaporation is partly a problem of reentrainment of the separated water due to inadequate drainage.

3 If it is assumed that the physical condition of the water-steam mixture on any boiler heating surface varies only with the rate at which heat is being absorbed by that surface, then the problem of moisture elimination is reduced to one of steam-path design applicable to boilers in general.

THE purpose of this paper is to describe certain studies of a specific moisture problem and to draw conclusions as to the causes of moisture entrainment from some features which were common to these studies. The problem was the reduction or elimination of moisture in steam from boilers operated at rates of 25 lb. evaporation per square foot of boiler and furnace surface, with 90 per cent make-up and with full chemical treatment in the boiler for the elimination of scale. The conclusions drawn from these studies are:

1 The concentration of the hydroxyl radical is a factor in the production of wet steam which acts independently of the rate of evaporation, or of the concentration, within the range of these studies, of other solid or dissolved chemical substances, and which has a critical value varying with the boiler design.

2 The production of dry steam at high rates of evaporation is partly a problem of reentrainment of the separated water due to inadequate drainage.

3 If the assumption that the physical condition of the mixture of steam and water on any boiler heating surface varies only with the rate at which heat is being absorbed by that surface is acceptable, then the problem of moisture elimination is reduced to a problem of steam-path design applicable to boilers in general.

This paper will of course offer data to substantiate the foregoing conclusions, but the author frankly offers the conclusions only as an incentive to discussion which, it is hoped, will awaken interest in the basic causes of wet steam and perhaps indicate the lines which future investigations should follow.

The author has had no intimate connection with a problem as baffling as that of moisture in steam at high boiler capacities recently completely solved at the Kips Bay Station of the New York Steam Corporation. The studies started in the early winter of 1927–1928 and were continued, under increasing stress, until January, 1929, when the essential solution was reached, the refinement of which is still in progress.

[1] Engineer, New York Steam Corporation. Mem. A.S.M.E.

[2] Presented at a meeting of the Metropolitan Section of the A.S.M.E., New York, N. Y., April 1, 1929.

The first series of studies constituted a search for variables, other than capacity, on which the moisture quantity depended. Water level was found to be a very minor factor in the problem within the range of normal operation. One or two studies showed reasonable and consistent agreement between variations in water level and variations in moisture, but for the greater number of the studies it was found that the amount of water-level variation normally occurring was not sufficient to affect the calorimeters, and the minor variations in this level were neglected during the remaining studies.

Rate of evaporation as a factor in the moisture problem was

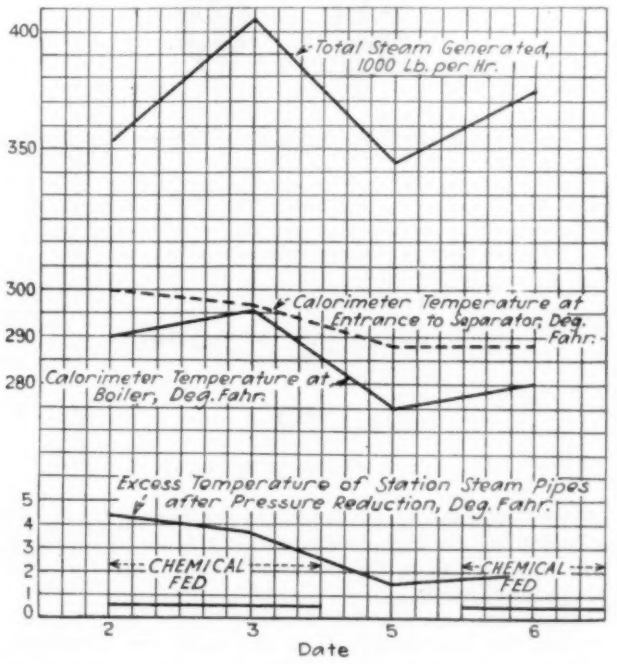

FIG. 1 RESULTS OF FOUR-DAY TEST TO STUDY THE EFFECT OF CHEMICAL ADDITION ON MOISTURE

neglected somewhat in the early studies because the calorimeter indications were not consistent. Some studies indicate less moisture at high rates than had previously been found at lower rates. These indications directed the studies toward the search for some other variable which was independent of rate of evaporation and on which the quantity of moisture depended.

The first variable studied was the design of calorimeters and sampling nozzles. It was found that the number of measurements of moisture in a given steam main varied directly with the number of different calorimeters installed, and also directly with the number of different locations of the same design of calorimeter and sampling pipe. There was erosion of the blading on the feed-pump turbines, yet there were calorimeters which indicated no moisture and others which indicated more moisture than the expansion of the steam could evaporate. Although it was felt that absolute accuracy in the measurement of the quantity of moisture in steam was practically beyond the reach of operating tests, we were not prepared for the unexpected

ability to indicate almost any desired quantity of moisture by slight alterations in calorimeter location or design. That this variation in moisture indication was a serious blow to our established understanding of the sensible conduct of such an investigation was evidenced by the fact that we actually spent considerable time searching for any factors other than moisture which might have caused the apparent erosion of the turbine blading. However, the calorimeter problem was eventually solved by standardizing both design and location on the basis

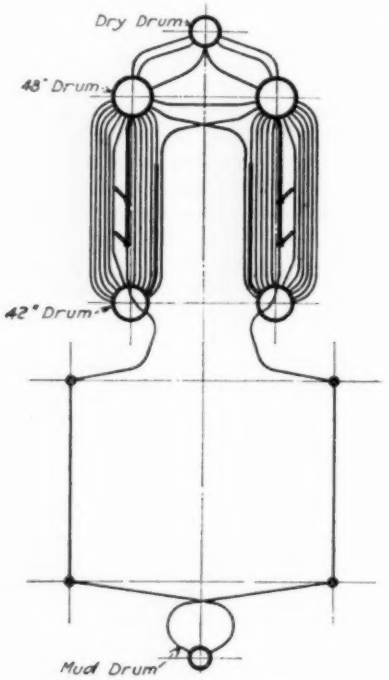

FIG. 2 ELEVATION OF BOILER

of the highest moisture indication of the various types. This standardizing was done in the hope that when such a calorimeter was made to indicate dry steam the turbine buckets would no longer show erosion.

About this time a second variable, that of the addition of chemical for scale prevention in the boiler, was investigated, and then temporarily abandoned as one of the factors in the moisture problem. The operators of the station found that there was apparently some connection between the rate of addition of chemical and the condition of the steam at gland leaks and trycocks in various locations. A test of four days' duration was then made, during which the operators varied the rate of chemical feed from zero to maximum without the knowledge of the test men so that personal opinions could be completely eliminated. The results are shown in Fig. 1, and indicate that the moisture was slightly greater when the chemical was fed at zero rate than when fed at maximum rate.

The curve at the top of Fig. 1 indicates the average rating on each of the four days of the test. The next two curves indicate the average calorimeter temperature at two points on each of the four days. The dotted curve shows the temperature in a calorimeter on the steam main just before the turbine separators, and the full curve shows the temperature in calorimeters in the risers from the boilers. The steam should be drier at the turbine separator than at the boiler riser by the amount of water drained from the mains through the drip lines, and therefore the relative position of the two temperature curves is reasonable. The two curves show no unreasonable difference in trend and therefore are corroborative. Our suspicion of calorimeters was based on the sampling error, so in order to eliminate it, in so far as possible, we took advantage of the drop in pressure from the station header to the street mains. This drop in pressure was about 130 lb. per sq. in., and was sufficient to evaporate approximately 1.25 per cent moisture. If the moisture was less than this amount then the pipe ought to be at a higher temperature than that corresponding to the saturation temperature. The surface temperature of the pipe was generally a few degrees above the saturation temperature equivalent to the operating pressure, and therefore the moisture in the steam before expansion was less than 1.25 per cent unless some unstable condition of supersaturation existed at the point of temperature measurement. Whatever the possible errors in the method, the curve showing the excess temperature has the same shape as the calorimeter curves above, and therefore we have further confirmation of the fact that there was more moisture in the steam on the third day than on any of the other three days. Chemical was fed to the system beginning at noon on the first day and continued for 36 hours. There was then a gap of 24 hours in which no chemical was fed to the boilers, and the test was ended with a 24-hour period in which chemical was fed to the system. The difference in the quantity of moisture indicated by calorimeter temperatures was so slight as to preclude any satisfactory conclusion, but at least it could not be said that the results indicated that the on or off position of the chemical feed valve was a factor in the moisture problem. We have said that the investigation of the effect on moisture of the addition of chemical to the feedwater was temporarily abandoned after this test, and this was the case, but in the light of the later studies it is evident that the abandonment was a mistake, because the chemical factor which influenced the moisture happened to have been kept below the critical point found later and was therefore not evident as a factor. Later when the studies, interrupted by construction work, were continued, the critical value of the hydroxyl radical was found, but in the interim the use of me-

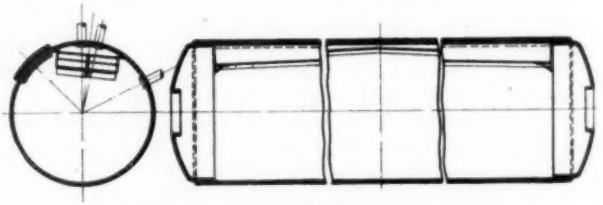

FIG. 3 BOX BAFFLE UNDER RISER TUBES

chanical means such as baffles, etc. to reduce the moisture was studied.

The only feature common to all of the baffle studies was the failure of each study to indicate an improvement in the moisture conditions. For this reason these studies are described only in so far as the type of baffle is concerned, and no attempt is made at this point in the paper to indicate why each type of baffle not only failed to solve the problem, but failed to improve the indications of the moisture condition sufficiently to warrant further study. Later an explanation of the failures will be offered to promote discussion.

Fig. 2 is an elevation sketch of the boiler and furnace presented to fix the locations of each of the six drums of the system. The top drum is 30 in. in diameter and has finally come to live up to its name of "dry drum." The next lower drums are each 48 in. in diameter and contain both steam and water. These drums are referred to as the 48-in. drums. The next lower drums are the 42-in. water drums, in which no work for these studies was done. The bottom drum is the source of water

supply for some of the furnace-wall screens and is referred to as the mud drum.

Fig. 3 shows the nature of the first baffle tried. This was a sheet-metal trough designed to force all steam rising from the boiler tubes to move to the ends of the 48-in. drums before entering the riser tubes and moving to the dry drum. Access to this trough was therefore through the ends, and egress through the top. The thought involved in this design was to change the path of the steam so that gravity would have time to remove the moisture while it was traveling horizontally. Apparently, however, it was ineffective.

Fig. 4 shows a baffle which was placed over the discharge opening of each upper water-wall header in the 48-in. drums. These baffles, of which there were four per boiler, were designed to prevent the steam and water discharged by the water walls from rising directly to the open ends of the box baffle shown in Fig. 3. The steam was deflected toward the center of the drum where it reversed its direction of flow, and mingling with the steam from the rest of the boiler, traveled back to the ends of the drum and entered the open ends of the box baffle. The thought was that the reversal of direction of flow would remove some of the moisture, but apparently the centrifugal force involved was not sufficient for the purpose.

Fig. 5 shows a louver-type baffle which was installed at each end of each 48-in. drum just inboard of the open end of the upper box baffle. This baffle was designed to induce the moisture to

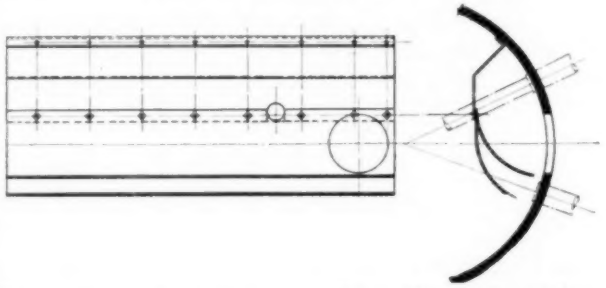

Fig. 4 Baffle Over Discharge From Upper Water-Wall Header

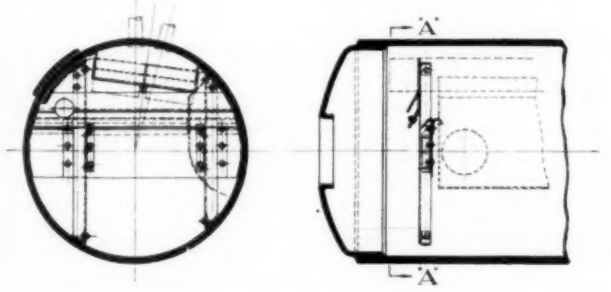

Fig. 5 Louver Baffle

give up its momentum in one direction and accept a new momentum in a new direction differing from that to be taken by the steam. Its action, however, was not of sufficient intensity to cause the indication of the calorimeters to change for the better from a moisture standpoint.

Fig. 6 shows some extension nipples which were connected to those tubes in the baffle row through which the steam and water from the bottom screen, front wall, and arch on each side reached the steam space of the 48-in. drums. In the belief that the long length of travel, due to the series connection of these portions of the furnace heating surface, might result in extremely high velocities at the exit of those tubes in the baffle row, which were connected at their lower end by internal drum connections to the discharge from the arch screen, extension nipples were added to avoid disturbance of the water in the 48-in. drums. One or both of two things must have been true, either the fluid issuing from the tubes was not as high in proportion of steam as was

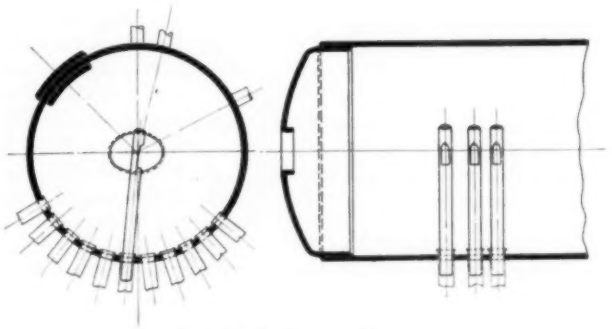

Fig. 6 Extension Nipples

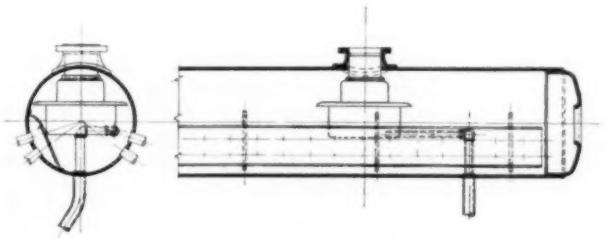

Fig. 7 Dry-Drum Deflector Baffle

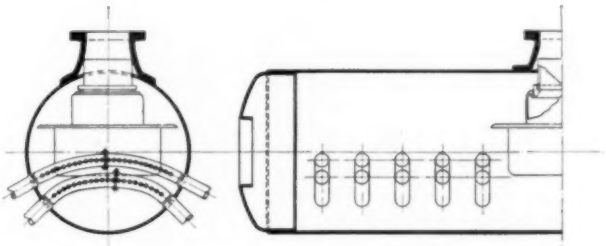

Fig. 8 Perforated Internal Connectors in Dry Drum

thought, or the density of the fluid in the 48-in. drums was so low as to be practically the same as the discharge from the wall tubes, because the calorimeters did not indicate any improvement. These nipples were installed after the baffles shown in Figs. 3, 4, and 5 had been removed.

Fig. 7 shows a simple deflector-type baffle which was installed over the ends of the riser tubes on each side of the dry drum. The designed purpose of this baffle was to deflect the moisture in the steam to the bottom of the dry drum where the drum drains would permit it to return to the 48-in. drums. This installation did not improve the reading of the calorimeters.

Fig. 8 shows a series of perforated internal connectors installed in the dry drum to join the ends of the delivery tubes on each side of the drum. The thought was that the difference in density between the moisture and the steam would cause the moisture to be trapped in these tubes and returned against the low velocity of steam in the riser tubes, to the 48-in. drums. A possible reason for the failure of these perforated connections as well as the failure of the deflecting baffle shown in Fig. 7 is that the amount of water separated from the steam in this drum exceeded

in amount the capacity of the existing drainage tubes, and therefore had no choice but to be reentrained and thus leave the boiler through the steam nozzle.

The author feels that the foregoing studies are logical applications of previous engineering experiences brought forward by several engineers who at one time or another were consulted on the problem. Most of the baffles represented types which had accomplished really satisfactory results elsewhere, and which could be reasonably expected to improve the conditions encountered at this plant, but they did not do so. All tests were made with care, and only one of the known variables affecting moisture was studied at a time.

Therefore, after having mentioned those studies the results of which were purely negative, it is more pleasant to describe others which produced positive results, and which eventually explained the success of the changes which solved the moisture problem.

Effect of the Concentration of Hydroxyl on Moisture

The first conclusion drawn from these moisture studies was that there was a critical value of the concentration of hydroxyl above which the production of dry steam was, to say the least, extremely difficult, and below which the hydroxyl seemed to have little or no effect.

Substantiation of this conclusion can be found in the data of practically every study made during the investigation, but rather than offer data which are only repetitive, but three studies are presented.

In each figure the average calorimeter temperature is plotted as a full line near the top of the chart with its ordinates at the left. Immediately below the temperature curve is a dash-line

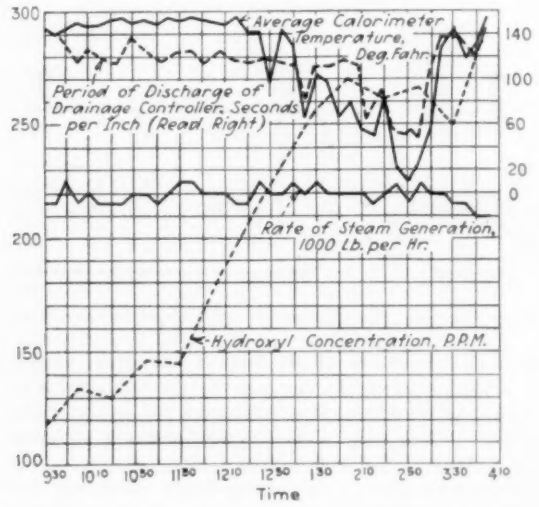

Fig. 9 Effect of Hydroxyl Concentration on Moisture

curve showing the number of seconds during which the drainage tank, for the station steam lines, filled one inch. This curve is merely a substantiation of the calorimeter temperature curve, inasmuch as the amount of water drained from the steam mains ought to vary with the amount of moisture in the steam. The ordinates for this curve are at the right of the chart. The lower full line indicates the rate of steam generation by the boiler under test. The dotted curve shows the concentration of hydroxyl in the boiler water.

In Fig. 9 are plotted the data of the first test revealing the relation of hydroxyl concentration to moisture. The calorimeter temperature was steady until about noon, when the conditions became unstable, and definitely indicated more moisture by 1:00 p.m. The steam increased in moisture until about 3:30 p.m. when it began to get dry. The calorimeter indications were substantiated by the record of the drainage tank, and the boiler rating is shown to have been held constant so that changes in the hydroxyl concentration must have been responsible for the variations. When the concentration of hydroxyl reached a value somewhere between 200 and 250 parts per million, the calorimeters gave indications of an unstable condition. As the concentration increased to about 260 p.p.m. the calorimeter temperature continued to drop, but as soon as the concentration decreased the temperatures rose again. The author left the

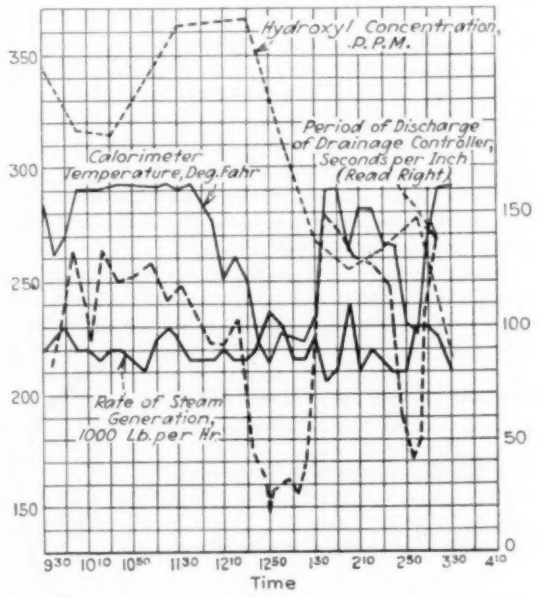

Fig. 10 Effect of Hydroxyl Concentration on Moisture

calorimeters at about 3:45 p.m. on this particular test to observe the nature of the leakage at the turbine valve glands. The conditions were apparently good but just after four o'clock moisture was indicated, and a hurried trip to the calorimeters showed a low temperature which was in agreement with the existing high hydroxyl concentration. The slope of the hydroxyl-concentration curve was changed by blowing down either through the steam nozzle or the blowdown valves. Evidently a lag exists in the relation between the concentration of hydroxyl at the steam-releasing surface and at the water-sampling point which, especially when the concentration is changing rapidly, causes a lag between the concentration and the calorimeter temperature.

In Fig. 10 the study was started with a high initial hydroxyl concentration which was reduced near the middle of the study and further reduced at about 3:30 p.m. The effect on the calorimeter temperature is evident and is confirmed by the period of the drainage tank. The concentration of hydroxyl was higher during the early stages of the study than the author believes it can be successfully carried without trouble. This condition has occurred on other tests but very infrequently, so that he feels that the discrepancy arises from non-uniform concentration due to circulation rather than from any other factor in the problem.

In Fig. 11 the calorimeter temperature, confirmed by the drainage tank, falls in irregular steps as the hydroxyl concentration rises, until the moisture increases sufficiently to stop further increase in hydroxyl concentration. The blowdown at about 12:30 p.m. reduced the concentration sufficiently to permit of

fairly constant calorimeter temperatures for the remainder of the study.

In the opinion of the author there is a critical concentration of hydroxyl the value of which, for these particular boilers, is somewhere between the limits of 220 and 250 p.p.m. None of the apparatus designed for moisture removal which was tested during these studies is sufficiently powerful to dry the steam when the hydroxyl concentration exceeds the critical value mentioned. The question which naturally occurs is, What is the value for other boilers? The author is able to offer Fig. 12 showing some of the data taken on a moisture test of a horizontal water-tube boiler of the box-header type. This boiler was fed with water containing a high concentration of sodium hydroxide, and measurements of steam quality as well as purifier-trap discharge were made to determine the effect of the hydroxide on steam quality.

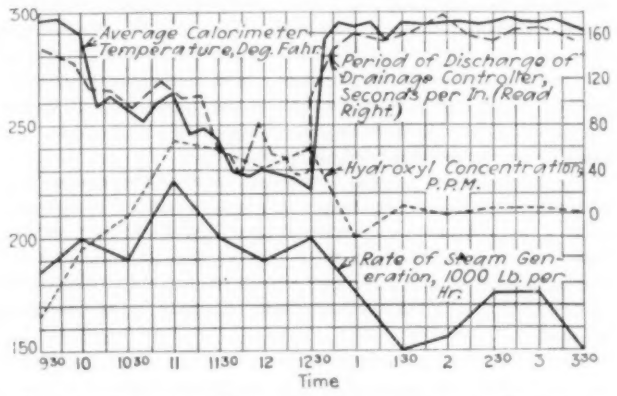

FIG. 11 EFFECT OF HYDROXYL CONCENTRATION ON MOISTURE

The trap discharge was mixed with cold weighed water and the temperature rise of the latter was measured. In this manner, assuming that the trap discharge contained only the heat of the liquid at boiler pressure, the quantity of moisture removed by the purifiers was ascertained. The mixture of trap discharge and weighed water constituted the boiler feed, so that the only loss of chemical was through the steam nozzle. Weighed quantities of sodium hydroxide were added to the feedwater and fed to the boiler. Assuming that the water capacity of the boiler was constant for the period of the test because the rate of steam generation was approximately constant, the concentration of hydroxyl in the boiler was computed from the known amount added. In Fig. 12 the full curve at the bottom shows the computed moisture in steam as indicated by a calorimeter. The dotted curve shows the purifier-trap discharge computed as a percentage of the steam generated. The dash-line curve shows the approximate hydroxyl concentration in the boiler, and the full curve at the top shows the rate of steam generation. The readings of water level are not shown but were of no significance because the water level was held practically constant during the entire test.

For the first two hours of the test the calorimeter read practically constant and indicated 0.5 per cent moisture. A constant calorimeter temperature is sometimes made the basis for the assumption of dry steam inasmuch as it is reasonable to assume that moisture is not present as a constant percentage, but this chart makes no allowances for this assumption nor for any base error in the calorimeter. Instead of the plotted value of 0.5 per cent, the moisture was more probably from 0.0 to 0.25 per cent.

The curve showing the trap discharge has an upward trend as the concentration of hydroxide increases, with intervening variations in almost exact duplication of the rating curve until the hydroxyl concentration reaches about 700 p.p.m., when there is a very sudden increase in the trap discharge to a peak of about 27 per cent of the steam generated.

Although no more moisture was leaving the boiler through the steam nozzle at this point of high trap discharge than had left it previously, the operating conditions became hazardous due to the hammering of the trap lines. The boiler rating was decreased rapidly and the trap discharge reduced by closing a by-pass so that part of the moisture was discharged through the steam nozzle.

The sharp change in the slope of the trap-discharge curve at about 700 p.p.m. hydroxyl concentration indicates that this concentration is critical for this particular boiler.

Neglecting any discrepancy in the accuracy of the measurements concerned with the determination of the concentration of hydroxyl, it is evident that in the bent-tube boiler the concentration of hydroxyl ion above which moisture in the steam increases in amount to a very excessive extent, is much lower than the similar critical concentration for the straight-tube header-type boiler. This indication of a critical hydroxyl concentration on the straight-tube boiler has not been confirmed by repeated observations, as has the value for the bent-tube boiler, but observations of moisture have shown excellent conditions with hydroxyl concentrations of 300 to 400 p.p.m., and previous attempts to build up the hydroxyl concentrations to the value of 1000 p.p.m. for corrosion-study purposes were entirely unsuccessful and led to the study shown in Fig. 12.

The author has found that the concentration of hydroxyl has varied independently of the concentration of other dissolved solids in the boiler water of the bent-tube boiler, and yet when the hydroxyl concentration has reached the range of the critical

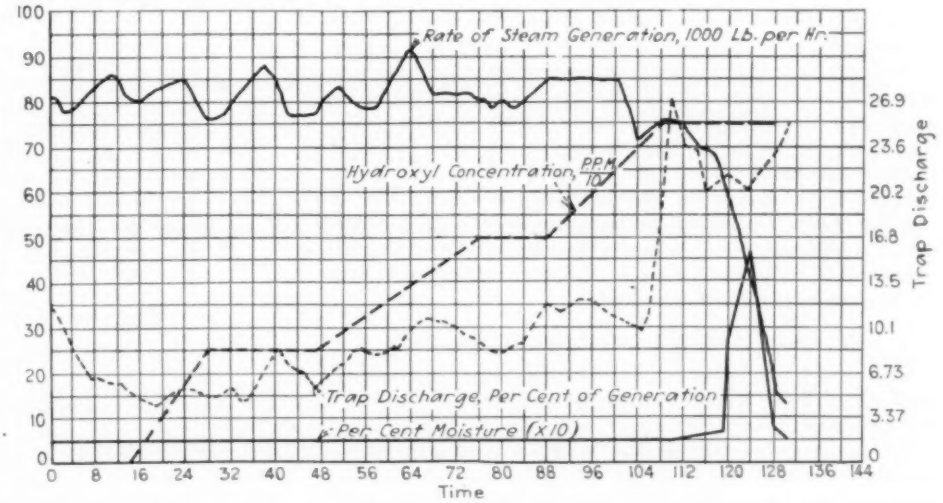

FIG. 12 EFFECT OF HYDROXYL CONCENTRATION ON MOISTURE—STRAIGHT-TUBE BOILER

value the amount of moisture in the steam has almost invariably increased. The effect of the critical concentration of hydroxyl has been the same in boilers just filled with raw water as it was on boilers which had been in the line for weeks, so that the effect of hydroxyl must have been independent of the concentration of suspended matter, which must have varied under the above conditions.

In the foregoing paragraphs it has been shown that the concentration of hydroxyl is a factor in the production of wet steam which acts independently of the capacity and the concentration of other solid or dissolved chemical substances, and which does depend on the boiler design. It may be said at this point, to forestall possible criticism, that several hundred concentrations of the raw water and the boiler water showed practically no organic matter when made acid and subjected to

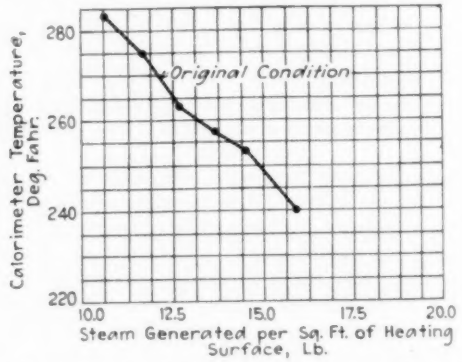

FIG. 13 CALORIMETER TEMPERATURE VARIATION WITH RATE OF GENERATION

ether extraction, so that saponification is not the obvious reason for the action of hydroxyl in this case. The physical or chemical reasons for such findings as have been indicated by the foregoing studies is, in the author's opinion, a good question to lay at the door of the laboratory specialists in these subjects because the complexity of the problem is beyond the range of power-plant work in the field.

The chemical side of the moisture problem, namely, the economic maintenance of low hydroxyl concentration, is at present under investigation, and the indications are that eventually the result will be to maintain a proper hydroxyl concentration without the existing excessive blowdown.

EFFECT OF RATE OF EVAPORATION ON MOISTURE

The second conclusion drawn from this series of studies is that the moisture is partly a problem of reentrainment due to inadequate drainage.

The problem of purifier drainage in plants whose percentage of make-up is of the order of 90 per cent is far more of a problem than in plants whose make-up is 5 or 10 per cent of their generation. Usually the high-make-up plant is a high-moisture plant, and one in which the exhaust from non-condensing auxiliaries is used to heat the raw water. The purifier discharge would generally be too great a quantity for an efficient continuous blowdown, and could not be returned to the feedwater heater without upsetting the heat balance. For the foregoing reasons internal drainage of purifiers was held to be a requirement of these studies and no thought was given to external drainage.

Fig. 13 shows the relation between moisture and rate of evaporation at the beginning of the capacity studies. The function can be said to be linear and shows a calorimeter temperature of 309 deg. fahr., at a 7.5-lb. rate of evaporation per square foot of boiler and furnace heating surface, dropping to the lowest calorimeter indication at a 17.5-lb. rate.

The condition of the unit at this time was exactly as originally installed. There were no baffles or other apparatus in the 48-in. drums, and only the original purifiers in the dry drum. These purifiers had proved their ability to dry steam containing as much as 27 per cent water during the study shown in Fig. 12 when the drains were connected to outside traps. As installed in the bent-tube boiler, however, the difference in elevation of the dry drum and the 48-in. drum was depended upon to provide sufficient head for purifier drainage without resort to traps and their attendant nuisances. We may call this natural drainage, and Fig. 13 indicates how effective this drainage was in removing water from the purifiers. The confidence warranted by past experiences, however, led to the application of means for draining the purifiers to a more complete degree than was possible by the natural head alone.

Fig. 14 shows the relation between the rate of evaporation and moisture after the drains from the purifiers had been equipped with a hydrokineter or aspirator supplied with part of the feedwater as a motivating fluid. There was an indicated decrease of approximately $1^1/_2$ per cent in the quantity of moisture at practically all rates of evaporation, due only to the change in drainage.

The hydrokineter or aspirator is working under somewhat unusual conditions when placed in the steam drum of a boiler, inasmuch as with any practical excess pressure on the feedwater passing through it, it is unable materially to reduce the pressure in its suction line. Any pressure reduction is accompanied by a temperature drop and a resultant transfer of heat from the steam space to the fluid being drained, so that evaporation

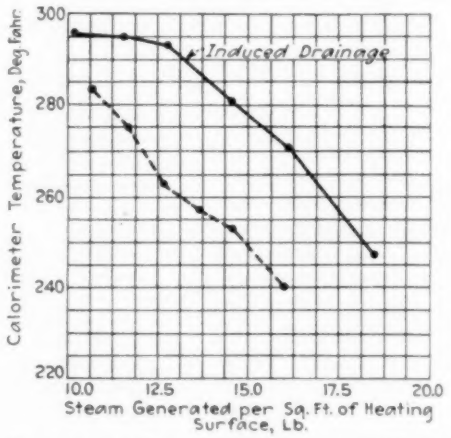

FIG. 14 CALORIMETER TEMPERATURE VARIATION WITH RATE OF GENERATION

takes place, replacing a comparatively inelastic fluid with an extremely elastic one. With this thought in mind the resistance between the purifiers and the aspirators was reduced by duplicating the drainage area of the purifiers and drain piping up to a short distance from the aspirators.

Figure 15 shows the results of decreased drainage resistance. The steam was commercially dry up to rates of evaporation of 17.5 lb. per sq. ft. The improvement was greater at the higher rates than at the lower, although there was theoretically as much room for improvement at the lower rates as there was at the high rates. The only possible conclusion was that there was a base error in the calorimeters which caused them to indicate about 1 per cent moisture when the steam was actually dry. Based on this assumption steam was thereafter called less than $^1/_2$ of 1 per cent when the calorimeters read 305 deg. fahr., or more, although the steam tables indicated that this temperature corresponded to about 1 per cent moisture.

About this time the dryness of the dry drum was investigated by installing some test-gage glasses. The first indications were that water was flooding the drums, and that the drainage system was entirely inadequate for the load placed upon it at these rates of evaporation. Water levels of sufficient height to cover the steam-riser tubes have been measured in the dry drum so that there was little or no possibility of steam leaving the boiler without reentraining moisture. The drainage area was increased to four times the original area, and this increase was sufficient to necessitate only an inch or two of water in the dry drum to provide the entrance loss into the drainage tubes.

Thus far in the studies of the relation of the rate of evaporation to moisture we have not actually inserted into the path of the steam any obstacles to the passage of water. However, because we have made those existing obstacles effective by removing the obstructed water from them, we have in effect installed obstacles which have changed the relation between the rate of evaporation and moisture.

Work was outlined to progress along these lines in the belief that the solution of the moisture problem rested in the separation of the moisture from the steam in the dry drum. The experimental work, however, had to adapt itself to operating requirements to an increasing extent as the winter load came on, and therefore progress was slow. Just after a particularly promising new arrangement of purifier drainage had made conditions worse, because of poorly welded joints at inaccessible locations, the makers of the boiler brought forward a new type of baffle for installation in the 48-in. drums. This baffle fitted into some ideas which had grown out of previous failures and consisted of a perforated plate placed at an angle in each 48-in. drum as indicated in Fig. 16.

The results with this baffle were so pleasing, as shown in Fig. 17, that all further work on the mechanical side of the moisture problem was dropped. The calorimeter temperature remained practically constant at ratings up to 22.5 lb. per sq. ft. of heating surface, and its value was such that the moisture can be said to be less than $^1/_2$ of 1 per cent.

Possible Explanation of Mechanical Results

We have seen that reasonable appearing obstructions to the passage of water mixed with steam failed to reduce the moisture; we have seen that a critical value exists for the concentration of hydroxyl which does not vary appreciably with the rate of working the boiler but which does vary with the boiler design and which has a pronounced effect on the amount of moisture in the steam; we have seen progressive improvement result from the effective use of existing obstructions to the passage of moisture; and finally we have seen the solution of the difficulty result from the installation of an obstruction which in most respects, other than results, does not promise the effectiveness of some of the baffles tried in the early studies. The application of a similar

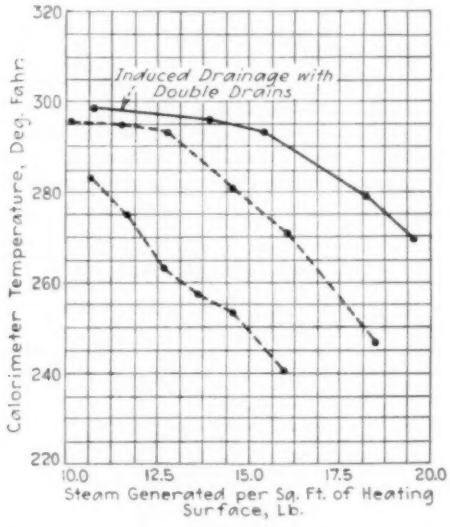

Fig. 15 Calorimeter Temperature Variation With Rate of Generation

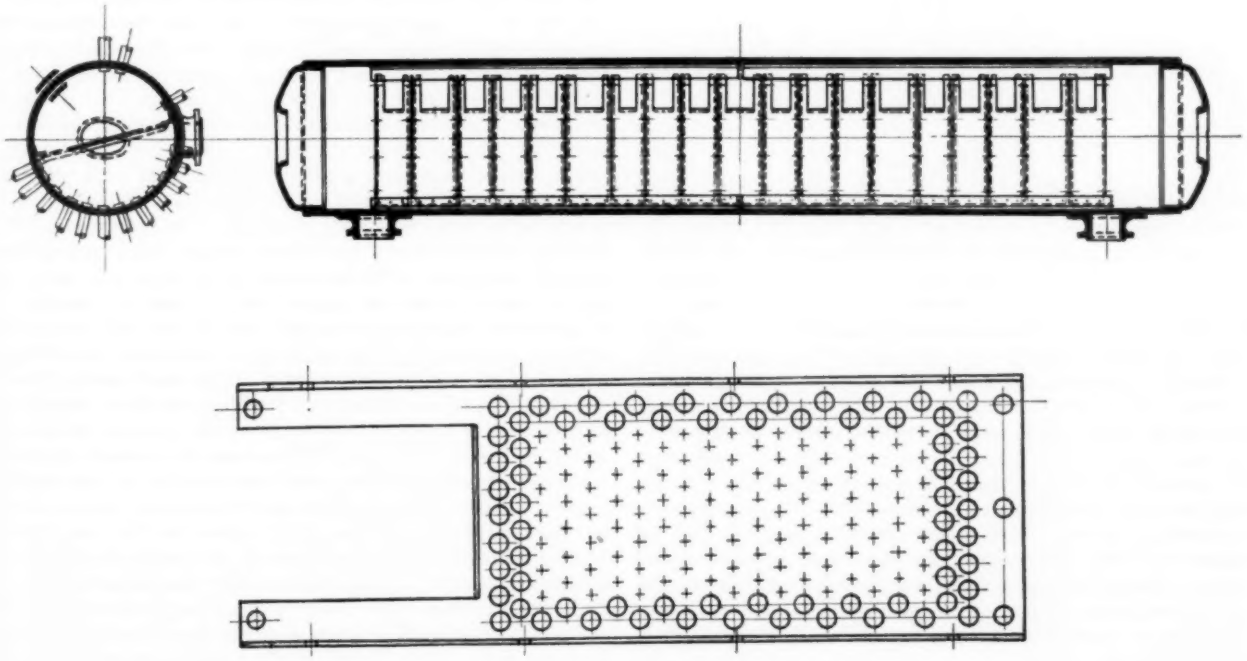

Fig. 16 Perforated Baffle

baffle to another type of boiler might or might not solve the moisture problem, and if we are to learn anything about the problem we must guess as reasonably as possible why one change improved conditions while another made no improvement.

In any consideration of separation of steam from large drops of water, space—or its equivalent, a decrease in velocity—is of paramount importance and probably of greatest physical effect. If separation is to be effective, the difference in density between the fluids is of importance, but of greater importance is the size of the droplets of water mixed with the steam. It is far more difficult to separate an emulsion than a mixture of larger particles of the same specific density from a given fluid, because as the particle size decreases the weight per unit surface area decreases very much faster, and because the surface area influences the resistance to the motion of the particle through the fluid. To expedite such a separation it is necessary to impinge the fluid on a target and coalesce the small particles into larger ones

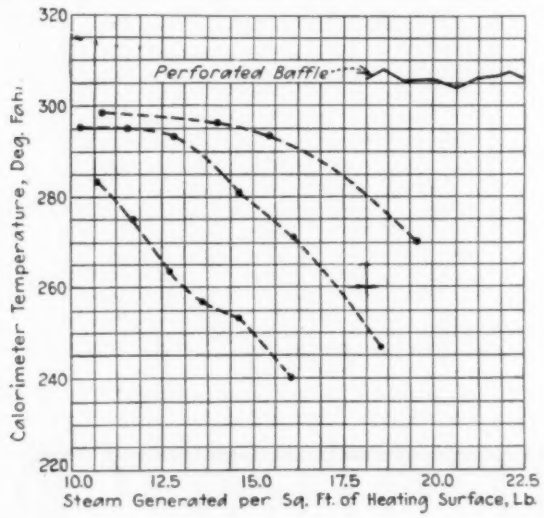

FIG. 17 CALORIMETER TEMPERATURE VARIATION WITH RATE OF GENERATION

of less surface area per unit weight, or to apply some fairly powerful centrifugal force to the fluid to help the coalescing. At Kips Bay or at any station with high rates of steam generation, it is extremely likely that the fluid delivered to the steam space is of the nature of an emulsion. The time necessary to separate the liquid and gaseous phases is probably greater than can be accomplished by simple enlargement of passages resulting in velocity decreases. Therefore the increase in drum sizes is probably not the answer to moisture. The impingement of the fluid on the walls of the tubes connecting the steam drums to the dry drum is effective in coalescing enough of the water in the emulsion to permit the larger droplets to separate in the dry drum, and, if the drainage is sufficient to return this moisture to circulation in the boiler, ratings of 15 lb. per sq. ft. can be carried with only this impingement as provision for drying the steam. With these thoughts in mind, the separation of the emulsion into its components phases calls for increased drum drainage and increased impingement action. The introduction of steam into the dry drum must take place above the level of water accumulation in the dry drum, otherwise reentrainment of of moisture will take place to an extent sufficient to overload any known purifier equipment.

If the foregoing theories or explanations of observed facts are acceptable, then the basic cause of moisture in steam is velocity in upcomers rather than the point at which upcomers are introduced into the steam drum. The velocity of fluid in upcomers as understood in this paper covers not only the physical velocity of the fluid but the nature of the fluid, which latter is dependent to a large extent on its velocity. In this case, therefore, velocity is intended to carry the significance of speed and emulsion.

To substantiate these explanations it is only necessary to refer to other boiler designs whose characteristics are well known compared to the design at Kips Bay. In any horizontal tubular boiler the velocities and the nature of the fluid is almost surely the same as at Kips Bay at points on the heating surface where the heat transmission is as great. However, if the path of the fluid from the lower row of tubes is followed, it can be readily seen that the fluid is subject to successive impingements on the walls of sinuous headers, on the staybolts of box headers, on the tubes leading to the steam spaces, and by meeting the fluid injected into the steam from other tubes. In addition the upper third of the tube bank invariably acts as downcomer area and returns the coalesced water to the boiler circulation without its passing into the steam space. Some such possible and probable explanation of the action of horizontal boilers is necessary to explain the ease with which the final separation is secured in such boilers. In vertical tubular boilers few are operating at ratings comparable with those at Kips Bay, but in all of them where moisture has been a problem the use of impingement has reduced the problem to one within the range of purifiers.

In one type of bent-tube boiler the impingement has been obtained by passing the steam from the front to the middle and thence to the rear drums through connecting tubes, and permitting that part of the emulsion which had coalesced to return to the circulation as it dropped out in the middle or rear drum. In cases in which baffles have been unsuccessful, it can be pointed out that the impingement was not serious enough or that insufficient provision for prevention of reentrainment was made. The next most important consideration to impingement is the removal of the coalesced water by drainage. The successful separation of the water from the steam after the emulsion has been coalesced necessitates a decrease in velocity in order that gravity may act, or if it is impossible to decrease the velocity sufficiently, some centrifugal action must be used to cause the separation in a smaller space.

The water-cooled walls of a furnace usually operate with an average rate of evaporation of 25 to 30 lb. per sq. ft. of exposed area. In the author's opinion, this rate of evaporation is sufficient to emulsify the fluid flowing through these tubes. In order that coalescing of such an emulsion takes place, it is necessary to provide a tortuous path so that the fluid will be subject to successive impingement actions after it has been removed from the heated zone. Increase in space or decrease in velocity, it seems, if the results observed are of any significance, will be insufficient to cause separation. However, because of the increased resistance of a tortuous path and the resulting retarding action on the circulation, a balance must be reached between impingement and resistance, and it will probably be found safer to provide most of the impingement between the steam drums and the so-called dry drums.

The foregoing thoughts are based on the assumption that the condition of the fluid in any boiler is the same at all points of the heating surface where the rate of evaporation is the same, and is of the nature of an emulsion of fine fog increasing in emulsification or fineness as the rate of evaporation increases. If this assumption is acceptable, then the moisture problem can be solved by designing the steam path so that the mist is coalesced into droplets separable by gravity. This coalescence can be accomplished by impinging the fluid at high velocity on targets or by combing the moisture through small apertures. The only other requirement is that sufficient drainage be provided to remove the water as soon as it is separated.

Discussion

N. Artsay.[2] The problem of moisture in saturated steam may be considered from the theoretical side. Many physical facts, laboratory experiments, and theoretical studies, especially those of Wilson and Stodola, indicate that the behavior of ideally pure water at a continuous rise of heat content will follow the Van der Waals' isotherms, i.e., the metastable conditions during the evaporation will be actually present.

In Fig. 18, that of the standard temperature-entropy diagram, the heavy full line represents the behavior of ideally pure water, the region A will correspond to the unstable state of superheated water, and the region B to the unstable state of undercooled vapor. On the pv diagram (Fig. 19) the metastable states are shown more clearly and are denoted by the same letters.

In a boiler the steam and entrained water present a mixture of the stable and unstable phases. The percentages of the two phases will depend upon the degree of water purity, the absence of nuclei of condensation, and the speed of evaporation or rate of heat absorption per unit of circulating fluid below the water level in the boiler drum. The entrained portion will depend upon the degree of impingement and turbulence produced above the water level in the boiler drum. The character of the moisture in commercial steam produced by the two causes will be entirely different. The entrained moisture consists of relatively large droplets having the temperature of saturated steam, while the moisture produced by the metastable phase will be in the form of minute globules of water at a temperature higher than that of saturated steam. Moreover the entrained moisture can be completely evaporated by a sufficient degree of nozzle throttling, while the metastable moisture can be eliminated only by throttling through a porous plug.

It must be borne in mind that the minute globules of water are in thermodynamic equilibrium with the surrounding superheated steam. Wilson's experiments on undercooled water vapor indicate that the maximum degree of undercooling in a mixture of dustless air and water vapor is 8. This means that in order to obtain condensation the absolute partial pressure of the vapor must be lowered adiabatically eight times from that corresponding to saturation pressure in order to break down the unstable state in the absence of extraneous nuclei. In Fig. 19 this represents $p_1 = 8p_2$ numerically. In the presence of extraneous nuclei the condensation occurs sooner in the sense of pressure; for commercial steam ejected from nozzles Stodola found the degree of undercooling to be from 3.2 to 3.5. The conditions of Wilson's experiments with a dustless air-vapor mixture means a persistent condition within the range of stable undercooling. Stodola's jet tests indicate that the degree of undercooling is lessened by the presence of nuclei but that it can persist also for an appreciable time. Wilson found also that ionized molecules can be centers of condensation, or are equivalent to extraneous nuclei like dust particles, for instance.

The reverse process takes place during evaporation. A perfectly pure water in contact with a polished surface will be superheated (points C) to the limit of the unstable state and then a certain part of it will flash into undercooled steam (points D). When the bubble is separated from the wall and begins to rise in the stream of circulating mixture of water and steam bubbles, gradually the undercooled steam will be heated up to the true saturation temperature if the time of travel in the water is sufficient, taking into account the size of the bubble. There are certain considerations which indicate that the heat transfer between the undercooled steam of the bubble and water is low, and hence in the case of very pure water we may expect a certain amount of undercooling in the drum if the boiler is perfectly clean and the circulation is rapid. This undercooling when it ceases after a time will produce a moisture content in the form of minute globules inseparable by jet throttling but effective in the adiabatic expansion.

At 300 lb. per sq. in. pressure the 3.0 degree of undercooling will give 2 per cent moisture, and at the 8.0 degree the moisture will rise to about 4.2 per cent. These are the limiting figures if no heating of the bubble takes place, and they may be read directly on the Mollier chart.[3] It is worth noting that at the critical pressure of 3226 lb. per sq. in. there is no separation of moisture because the metastable phase is impossible. Hence Wilson's limit for undercooling of 8 must locate the maximum value of the saturation curve on the Mollier chart, the value being 3226/8 = 403 lb. per sq. in. abs., while the Keenan chart puts this point around 420 lb. per sq. in., or the points coincide within less than 0.1 B.t.u. per lb. of heat content in the steam. This condition means zero content of both the metastable

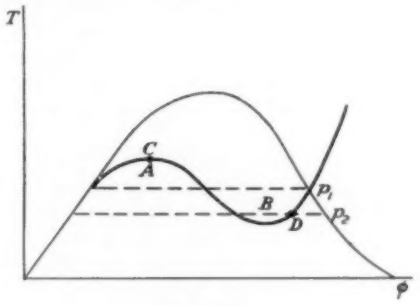

Fig. 18

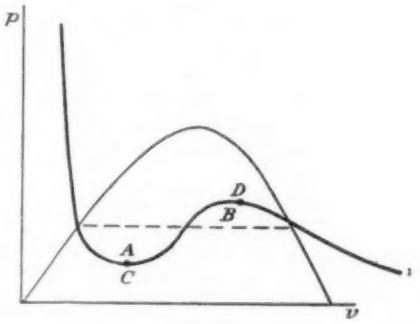

Fig. 19

phases. Wilson's value for the limit of undercooling is a corrected experimental value, but there are also theoretical considerations which indicate that it is uniform for all liquids with more or less symmetrical molecules.

Thus we come to the conclusion that a clean boiler with ideally pure water will deliver saturated steam with moisture content between 0 and 4.2 per cent if running at 300 lb. per sq. in. absolute pressure. This moisture will be in the form of minute globules of water, and impossible to detect by nozzle throttling but detectable in an adiabatic expansion. Now let us take an actual boiler evaporating water containing solid particles in suspension. The rough walls of the boiler tubes will prevent the superheating of water but will not prevent the undercooling of steam in an expanding bubble. Simultaneously the size of the bubbles will be very much reduced. The presence of solid particles and of ions in the bubbles will reduce the degree of undercooling, and we can reasonably expect a drier steam from an actual boiler if the steam is tested for moisture in an adiabatic

[2] Consulting Engineer, New York, N. Y.

[3] Up to 1000 lb. per sq. in. in abs. For higher pressures the heat of the metastable phase is in the form of superheated moisture; this was observed on certain high-pressure boiler tests.

expansion. But in an actual boiler there is another feature which counterbalances the effect of rough walls and of solid particles: the bottom tubes or ends of tubes are usually 10 to 40 ft. below the level of the water in the drum, which means a rise of the boiling point of from 1 to 4 deg. fahr. for boilers carrying 300 lb. pressure. Hence the water which passed these low points in circulation will rise again in a slightly superheated state.

The excess heat will produce additional evaporation which will increase the size of the bubbles already formed, and also produce new minute bubbles around nuclei furnished by the suspended solid particles. The latter fact is most important. The greater the number of nuclei per unit volume, the smaller will be the size of these minute bubbles and the more difficult their separation from the water. It is easy to see that at a certain specific concentration of nuclei in the water volume and a corresponding rate of heat absorption per unit mass of circulating fluid, the latter may become emulsified, causing so-called priming. We see also that the chance of priming is the greater the less the height of the boiler, because the bubbles will be smaller due to less superheating of water. These considerations if applied to the drum itself will furnish the explanation of foaming.

In all these considerations we must remember that the smaller the bubble of steam the more difficult is its separation from water and its ascension to the releasing surface in the drum, and hence the greater the chance of its being drawn down by the circulation, which recirculation will increase the emulsification. As mentioned before, according to Wilson, the ions act as nuclei in condensation, and we can assume that they act as nuclei in the evaporation of superheated water.

The moisture observations of the author made by throttling calorimeters must be accounted for by the entrained moisture, while the effect on the turbine blades is the combined effect of entrained moisture plus the moisture of adiabatic expansion separated on the much more numerous nuclei of the moisture generated by the described process in the superheated water and undercooled steam.

The existence of a critical value for the hydroxyl content may be explained in the following manner. First the hydroxyl content or degree of ionization must be regarded as additional to the nuclei furnished by the solid particles. With rising concentration of hydroxyl the effect of the latter will produce, first, the hidden moisture from the metastable phases and the minute bubbles of steam, which will tend to increase the degree of emulsification of water. At this period the entrainment of large droplets is approximately constant if the rating is maintained, the size of bubbles is appreciable, and their coalescence is possible. Beginning with the "critical" value of concentration, the bubbles formed around the nuclei are too small to coalesce, and broken films of emulsified water will be thrown into the drum, these films being easily picked up by the moving steam, and the entrained moisture content will rise sharply. The coalescing of the bubbles is greatly affected by *turbulence* in the boiler tubes, and hence the greater the velocity of steam-water mixture in the tubes, the larger the bubbles of steam will be. In general, apart from the size and design of the boiler, the velocities in the tubes will be an inverse ratio to the mean density of water-steam mixture in the boiler. The horizontal-tube boilers usually have a reversed flow in part of the top tubes, and this means a recirculation of steam in the circuit which lessens greatly the average density of the mixture. Hence boilers of the B. & W. type will give a larger-sized bubble, and the degree of emulsification will therefore be less and the steam drier. This consideration is amply substantiated by the observations of the author.

GEO. A. ORROK.[4] The author has given us a most interesting account of the solution of a troublesome problem which all operating men meet from time to time. We may lay the trouble to bad feed, improper dry pipes, or circulation overloads, but in the end we come back to the concentration of salts in solution in the boiler water. We have long known that at low pressures and ratings concentrations as high as 3000 grains per gallon are perfectly feasible, while at 250 to 300 lb. and evaporations of 10 lb. per sq. ft. of surface, 300 grains per gallon is perhaps the maximum allowable. The salts in boiler water are nearly always alkaline, a condition conducive to the formation of colloids, which may cause a major portion of the trouble. The author reports that no signs of saponification were found, but colloidal solutions exist without either soaps, starch, or other organic compounds, and they also occupy the ground between solutions and saturated gases. The steam might thus carry large percentages of liquid and solid matter in colloid form not susceptible to any ordinary separating action. Since colloids are solutions of particles coarser than molecular size, we avoid trouble by keeping boiler-water concentrations as low as possible, using mud-drum and surface blow-downs, deconcentrators, and other devices. If by any means these very fine particles can be agglutinated, the colloids will be broken up and the solids can then be removed by filtration. It would appear that the reducing of the hydroxyl concentration was one of these methods.

W. A. SHOUDY.[4] There is little that can be added to this paper, except by way of substantiation. It was the writer's good furtune to be associated with the author during the last period of the investigation described, and he consequently wants to take this opportunity of expressing his appreciation of the manner in which it was carried on, and the belief that the author has done toward solving this important problem.

Like every one else associated in the work, the writer immediately offered a solution based upon sound engineering information as it existed last year, but that solution was tried, with a resulting higher moisture content than existed previously.

The fact that there are now on the market so many steam purifiers is evidence enough that moisture in steam from boilers operating at high rates of evaporation is a serious problem. There are very few published data upon which the engineer may base any conclusions for solving this problem. In the author's opinion, the moisture problem is far more serious than we are willing to admit. The majority of boilers are equipped with superheaters, and these, except in extreme cases of moisture, tend to hide the trouble. To be sure, eventually this moisture content shows up in the superheater as scaling or other troubles, but quite frequently the operator is not aware of this fact for a considerable period of time.

The problem which the author discusses is probably one of the worst that any boiler operator has had to meet. These boilers were operating under extremely high rates of evaporation, which alone has a tendency toward production of high moisture content, but when added to this high rate of evaporation we have water which is 95 per cent make-up, and with full chemical treatment, we have a combination which is very difficult to analyze. Without the careful, painstaking elimination of variables in this analysis as carried on by the author, no solution would have been reached.

We have always attempted to eliminate moisture from steam by a sudden change in direction, when the steam was moving at a relatively low velocity. The elimination of the water was obtained by impinging on a baffle, so arranged that the path of the steam could not again pick up the water.

---

[4] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

In the writer's opinion the author has brought out the fact that the size or condition of the drop of water varies with different types of boilers. If these drops are extremely small, they cannot be separated by any standard methods except by a reduction in velocity so low as to make the separator impractical. If these drops can be made large enough to fall out by gravity, baffles and dry pipes will function.

The second important point which is brought out is that the hydroxyl radical has a greater influence upon priming than has concentration. We have all known that the degree of concentration was not necessarily an indication of priming, and although the author has not proved that the hydroxyl radical is the only reason for priming, he has indicated that at least under one set of conditions it is a direct indication of priming. It is to be hoped that studies of different waters will be made by others interested in the subject, and it is possible that such studies may result in a different control of priming.

G. K. Saurwein.[5] The writer had had experience at a number of boiler houses in by-product coking plants where very little condensate is returned to the boilers. Most of these plants are located in the South and have bad water supply. The water is treated by the hot softening process and filtered before it is fed to the boilers. The concentration in the boilers is controlled by continuous blowdown through orifices in bypasses to the blow-off valves. Blowdown rates as high as 8 per cent of the boiler feed are used, but this clears up all trouble from salts carried over into the superheaters, piping, and steam-using equipment.

The fuel here is surplus gas and coke breeze which in most cases does not warrant the installation of heat-reclaiming equipment. Simple heat exchangers can be applied to recover the heat in the blowdown, thus giving good boiler operation without this waste of heat.

Without having seen the curves and sketches of the paper, the writer would say that he agrees with its findings as expressed in the conclusions at the opening of the paper.

As the concentration increases, the ebullition tears away and the steam carries with it particles of the water, and the only way to remove these particles from the steam current is to provide sufficient baffles upon which the drops may impinge and coalesce into larger drops which will gravitate back into circulation. The steam velocity, moreover, must be sufficiently low so that these drops will not be reentrained. A velocity of 1000 or 1200 ft. per minute will entrain good-sized drops.

Gravity and centrifugal force never "go to sleep on the job" despite the author's discouragements. But they are working against tremendous odds in the turbulence that exists in the steam-relieving spaces in the boiler at these high steaming rates.

At evaporative rates of 4 to 5 lb. per sq. ft. customary a few years ago, the boiler constructions offered then served well enough. The lamentable fact is that the leading boiler manufacturers still offer the same old construction for steaming rates five times as high. The user is left to work out of his trouble by installing special drum baffles, etc., or is compelled to purchase auxiliary devices for drying his steam. If he wants superheat, his difficulties are further increased.

There is great need for development work on the part of the boiler manufacturer to make his equipment suitable for present methods of operation.

Author's Closure

The nature of the chemical conditioning of the boiler water at Kips Bay Station is such that the dissolved material is thrown out of solution under conditions which are not conducive to crystalline growth. The result is that finely divided suspended material is always present, and this would undoubtedly provide innumerable nuclei for the development of minute bubbles of steam. This condition caused the author to consider the fluid circulating in the boiler as having the nature of an emulsion with the accompanying difficulties of separation.

The action of ionized hydroxide may be considered as an addition to the number of nuclei, but the effect of an ionized particle may be somewhat different from that of a solid particle in suspension. The continuation of studies since the presentation of the paper has indicated that with chemical reduction of hydroxyl concentration and consequent relative increase in the concentration of suspended matter, the critical value of hydroxyl concentration has not changed. If ionized particles had nearly the same effect as solid particles, the author believes that a relative increase in the concentration of suspended matter ought to reduce the critical value of the hydroxyl concentration. Such a change has not yet become apparent at Kips Bay Station.

The existence of slightly superheated particles of water in contact with steam as indicated by Mr. Artsay may explain the results shown in Fig. 1. Using the reducing valves as throttling calorimeters indications were that the steam from the boilers was commercially dry although conditions at other points in the system indicated that the term "commercially dry" would not include the amounts of moisture found in the steam.

The possibility of colloidal material in the boiler water becoming a factor in the moisture problem was one of the phases which the author shied away from in this work. It was known that some material, possibly colloidal, was present in the concentrated boiler water, but the intricate studies involved in determining what part the colloids played in the problem were beyond the range of practical work in the field. Under conditions where operation must continue and only such technical work as is essential is practically permissible some attractive phases of such an investigation must be omitted and handed on to the laboratory specialists who have the equipment and time to determine properly how each phase fits into the general problem.

The moisture problem discussed in this paper was productive of many discouraging failures. Mr. Shoudy came in on the problem at the low ebb of experimental results when the non-productive nature of the gradual elimination of one variable at a time seemed likely to extend the studies over an uneconomically long period. The author wishes to express his thanks and that of his co-workers to Mr. Shoudy for his support of the program, and his helpful suggestions in the realization of the solution.

The value of results from an individual plant with particular governing conditions is small unless the results are interpreted and broadened by similar studies under other conditions. The author hopes that such studies will be made and the results interpreted so that the boiler designers may apply them to the improvement of their product with especial reference to capacity.

The thought that low velocity is essential to proper separation of entrained water is the correct basis for attack on the problem of moisture in steam. However, an examination of the cost of boilers indicates that approximately 80 per cent of the cost is represented by drums in a multidrum boiler. To reduce velocities the drums must be increased in diameter and shell thickness if the tube spacing is maintained. The problem of changing design so that lower velocities may be realized is extremely involved, and may offer serious obstacles under existing competitive conditions.

The author believes that the problem can be solved without increasing drum sizes by proper design of steam path so that moisture particles will be coalesced into separable drops without the expense of velocity reduction.

Salt Lake City's Fuel and Smoke Problem

A Review of the Current Situation

By GEO. A. ORROK,[1] NEW YORK, N. Y., and W. H. TRASK, JR.,[2] SALT LAKE CITY, UTAH

This paper is an attempt to set forth the smoke and dust conditions in Salt Lake City, discussing the various plans by which an improvement might be secured. In this connection, district heat, gas firing with natural gas and coke-oven gas, and the use of the products of low-temperature carbonization and the by-product coke oven are discussed and evaluated. The connection between the prosperity of Salt Lake City, the State of Utah, and its coal-mining industry is indicated, and certain conclusions looking toward the solution of the problem are stated. The whole discussion in the paper is preparatory to a discussion on the floor of the meeting which it is hoped will clarify the state of opinion regarding this problem in Salt Lake City.

SALT LAKE CITY is unique in many ways. Its population, 155,000, is the largest in the Interior Basin. It is the capital of the state of Utah and has a large industrial population. Within its borders are 25,000 homes, about 14,000 of which are occupied by their owners. The city is laid out on the valley floor at the mouth of the City Creek Canyon, down which flows City Creek, with the outlying ranges of the Wasatch to the north and east, while to the west the valley slopes gently across the Jordan River to Salt Lake, 16 miles away. The site is attractive; the soil, when given the proper amount of water, is most fertile, and it is no wonder that the early pioneers, after passing the defiles of the Wasatch, thought they had reached the promised land. The original city plan, ten-acre-square blocks, with wide streets and the creek diverted to throw a stream of water down each side of each street, has been extended far beyond the original boundaries to meet the expanding growth of the city and its change from an agricultural patriarchate to an industrial city. The early household fires of sagebrush, with mountain mahogany and other woods laboriously carted from the mountains, have been replaced by the boiler and industrial furnace fed with coal from Carbon County, just as the toiling prairie schooners which slowly traversed the dusty trails have been replaced by the Iron Horse fed with the same Carbon County coal.

The climate of the Salt Lake Valley is the ordinary 40th parallel climate of the north temperate zone modified by the altitude, about 4350 ft. above sea level, and the desiccation of the Great Interior Basin: cold winters, warm summers, little rainfall, and that mostly in the three winter months. In earlier times the cool mountain winds rushing in to take the place of the hot air rising from the heated plains swept the dust and smoke over the lake to the desert beyond. But when December came and the plain was frozen there was no return breeze, and the sagebrush smoke hanging low over the city is remembered by many who were there as late as 1890. The smoke from Utah coal was noticeable at that time, when less than 2 per cent of the Utah coal mined up to date had been produced. But thinking of the winter months of 1890 brings the sagebrush smoke of that time to mind.

Presented at the Semi-Annual Meeting, Salt Lake City, Utah, July 1 to 4, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Annual Fuel Consumption of Salt Lake City

Salt Lake City now burns over 700,000 tons of Utah coal per annum, and the smoke nuisance in the winter months is of course immeasurably worse than in 1890. Winter storms may disperse the cloud for a time, but the city is not free from trouble until the mountain winds start again in the spring with the warming up of the plain. While the smoke problem is the worst in winter, the dust problem from coal is also of major importance. Experiments have shown that from 1 to 3 per cent of the coal fired in furnaces of all kinds goes up the chimney into the air, and household fires are even worse offenders in this respect than some industrial plants. The economic loss from smoke is not large, of the order at maximum of 1 per cent, but the dust thrown out is largely unburned coal and coke with some ashes, and in some experiments amounted to over 4 per cent of the combustible. In large plants most of the dust can be caught by dust catchers of various forms, and well-run industrial plants with good dust-catching devices reduce this loss to less than $^1/_2$ of 1 per cent. Smoke, on the other hand, is most difficult to catch; its formation must be prevented. Modern industrial furnaces are designed to do this in a measure, but any high-volatile coal introduced into a hot furnace will smoke even when a most intimate mixture of air and the products of coal distillation is secured. The black, tarry vapors thus produced are persistent and most troublesome. Cleaning fires, which must be done at intervals during the day, always increases the amount of smoke and dust, although proper supervision can reduce this source to a minimum.

The City Council of Salt Lake has an ordinance prohibiting the production of black smoke, defined as No. 3 on the Ringelmann scale. Inspection of plants, observations from the smoke tower with telephone connections to the visible plants, and active cooperation with owners and operators of plants and railways together with the installation of stokers have reduced the smoke from industrial sources since 1919 by 93 per cent. It is considered that 70 per cent of the smoke at present comes from household fires, with comparatively slight chances of much reduction except through a change of fuel. Leaving aside the industrial use which is roughly 400,000 tons per year, there are 300,000 tons of coal burned by 25,000 families and served by at least 50,000 chimney flues from kitchen stoves, furnaces, and open grates. It is obviously impossible to exercise even a general supervision over such a number of prospective offenders, particularly as it is dark when they are most likely to offend. This is the problem as it stands today. And it is the purpose of this paper to place before this meeting and discuss the possible solutions to this problem.

Problem of the 300,000 Tons of Domestic Coal Used in a Year

The 300,000 tons of domestic coal heats the 25,000 buildings, runs the culinary departments for 25,000 families with some assistance from the gas and electric companies, and furnishes many "comfort" fires. The 400,000 tons of industrial coal supplies the locomotives and fires the boilers of a hundred or more industrial plants, mills, brickyards, smelters, and other metallurgical industries, laundries, printing establishments, etc., the district heating stations, and the gas works. These industrial establishments are few in number as compared with the 25,000

buildings, and their chimneys are well marked and can be kept under rigorous inspection. Moreover, stokers, dust catchers, and smoke-abatement devices are in use, and their numbers and efficiency can be augmented. It would appear that it is with the household use of 300,000 tons that this discussion is most concerned. And here a new element has entered into the problem. The Public Utilities Commission last January granted permission to the Western Public Service Corporation to lay pipe lines and import natural gas into Utah, and these lines will be brought into Salt Lake, the price to the user to be 50 cents per 1000 cu. ft. for all gas used above 5000 cu. ft. per month. If all householders would at once change their furnaces and stoves from coal-burning to gas-burning apparatus, all of the dust and

Coke Fuel Available

At Provo, 45 miles south of Salt Lake City, the Columbia Steel Company has a bank of coke ovens where they manufacture by-product coke for use in metallurgical furnaces. Small-sized by-product coke, nut and stove sizes, is a most excellent household fuel for furnaces, stoves, and open grates. Over 8,000,000 tons of this coke was sold in the United States for domestic fuel in 1927, and the use is increasing at a rapid rate wherever it is possible. An additional bank of 40 ovens installed at Provo or nearer Salt Lake City would easily supply the entire domestic consumption. Such a bank of ovens would cost with all auxiliaries roughly $2,500,000, or if built next to the Columbia ovens, using their by-product plant, might cost $1,750,-

Fig. 1 Airplane View of Salt Lake City Taken From the Northwest

much of the smoke from the 300,000 tons of domestic coal would be eliminated. The use of natural gas is not absolutely non-smoke-producing, since an inadequate supply of air results in the production of lampblack. As a matter of interest, 10 per cent of the entire natural-gas production is used in the manufacture of lampblack, and the gas flame is made to smoke for that purpose. Under this plan the Salt Lake domestic-fuel bill instead of being roughly $2,500,000 would be $4,000,000 at least, not considering the cost of changing over to gas burning, which might be set off against the present ash-removal and handling cost. There is no doubt, however, but that the production of smoke would be practically eliminated.

000. Incidentally the coal-mining industry would be called upon to furnish 150,000 tons more coal per annum, and about 3,000,-000,000 cu. ft. of 560-B.t.u. coke-oven gas would be available for metallurgical and domestic use. The cost of the coke at Salt Lake City should not exceed the $8.50 now paid for domestic lump, and no change would be needed in the furnaces, stoves, and grates. Smoke would be very much reduced, but the dust would still be present though in somewhat diminished quantity. If the time of coking could be shortened so that the 2 per cent of volatile matter would be increased to 4 to 6 per cent, a free-burning fuel would be secured for domestic use. This is quite possible in practice, increasing the output and reducing the

cost of operation. Coke is also a good fuel for industrial furnaces, but the price differential would probably prevent its use.

The Utah Oil Refining Company, as a by-product of its business of refining petroleum, markets about 10,000 tons of oil coke per year. This petroleum coke with its 5 to 6 per cent of volatile matter and little ash content is a most excellent smokeless fuel for household purposes. It should be crushed to the small stove size ($1^1/_2$-in. lumps) for the best results. More than 1,000,000 tons of this fuel is sold in the United States per annum. This is a luxury fuel for stoves and open grates and is readily absorbed. Coke-oven gas (560 B.t.u. per cu. ft.) is now largely used in city gas distribution, either by itself or mixed with coal gas, water gas, or natural gas. Being obtained as a by-product from the manufacture of metallurgical coke, the price at which it is sold to the city gas companies is quite low, averaging not far from 20 cents per 1000 cu. ft. Even when distribution costs are added, the public has usually benefited by a lower gas rate where this gas has been introduced. Oil gas has a much higher B.t.u. value, does not mix as well with other forms of gas fuel, and has not been so available for city gas use.

FIG. 2 HUNTS POINT COKE-OVEN PLANT, CONSOLIDATED GAS CO. OF NEW YORK

POSSIBILITIES OF LOW-TEMPERATURE-CARBONIZATION PRODUCTS

Many low-temperature-carbonization processes are in use in Europe and at least half a dozen are commercial, although few dividends have been paid. In this country no process has as yet been commercially successful, although a number have made good fuel and scientifically have been workable processes. The McEwen-Runge process now under trial at Milwaukee is not suited to the production of a household fuel, but the K.S.G. process under construction at New Brunswick, N. J., has this particular end in view though the main product is gas. However, none of these processes have been tried on Utah coals, and he would be a bold prophet to claim success in an untried field in a shorter time than eight or ten years. In England, Sir Geo. Beilby, starting in 1918 on the Fuel Research process, carried it along till his death in 1923. His successor, Dr. C. H. Lander, stated last November that he has 40 ovens in service, but does not expect to be able to call the process commercially successful short of three years. Meanwhile, five or six plants of constantly increasing size have been built, tried out, and replaced until he hopes the present plant of 40 ovens at Kingston-on-Thames will show a commercial profit and pay dividends. The financing in this case, started by the English Government as a war measure, has been carried on partly by Government funds and partly by the London Gas Light Company. The coke produced is an excellent fuel, suitable for the English grate fires, and they have had no difficulty in disposing of their available product. Whether the process would work on Utah coals

is not known. Dr. Lander also says that in general the by-products have shown no advantage over the by-products from the high-temperature coke oven.

Among the American processes the carbo-coal process also originated as a war measure and was financed by the Government. After the improvement of the retort by McIntire with the aid of private financing, a considerable amount of good household fuel was turned out and sold at or about the anthracite price as an anthracite substitute. This process is scientifically workable but has never been able to make its own way and is now shut down. We may conclude that low-temperature carbonization, especially with Utah coals, would have too much experimental work attached to it to bring relief within a reasonable time.

Trent-Process Briquets

During the war another very interesting type of process became known through the experimental work at the Bureau of Mines. This is the Trent process, which takes advantage of the fact that finely powdered carbon is readily wet by certain grades of oil while earthy particles remain suspended in the aqueous solution. The coal is finely ground with about 50 per cent of water, the resulting pulp is thickened, from 5 to 10 per cent of oil is added, and the whole mass is violently agitated. The coal particles are agglutinated into a pasty mass called the amalgam, while the water and earthy particles drain away. The amalgam is a fair fuel in this state, but is smoky owing to the oil which is used as a binder. The amalgam is then passed through a brick machine under considerable pressure, extruded through a nozzle, and cut off into bricks or small briquets. These briquets pass through a retort, which drives off a large portion of the oil, to be condensed and used over again, leaving a hard, semi-porous briquet which burns like the best anthracite coal. This briquet will stand transportation, is low in ash, and makes an ideal household fuel for stove or grate. The experiments at the Bureau of Mines have shown that some Utah coals are suited to this process.

Experimental plants of some size have been installed at Alexandria, Va., Providence, R. I., Toledo, Ohio, and Newark, N. J. The amalgam has been sold in bulk, amalgam bricks weighing 20 lb. have been wrapped in paper and sold for household fuel, and partially coked and fully coked briquets have been sold as an anthracite substitute. However, only the fully coked briquet is smokeless, and with this fuel the dust is much reduced. The complete process has not been tried out on Utah coals, and it is still a question whether in coking the briquet the smoke-forming constituents of the Utah coal would be broken up and driven off to such an extent as to leave a smokeless fuel. Such a plant capable of delivering 300,000 tons of briquets per annum might cost $1,250,000, would use at least 350,000 tons of slack coal which might cost $3.50 per ton, and would require a supply of oil equivalent to about $1 per ton of briquets produced. The margin between this cost and the price of domestic fuel would appear to be sufficient to insure a profit for the undertaking.

Fig. 3 K.S.G. Process Plant, Combustion Engineering Corp., at New Brunswick, N. J.

District Steam Heating

Many communities noted for their freedom from the dust and smoke nuisance are served by the district steam-heating systems which have been increasing in numbers during the last few years. Freedom from smoke and dust means that every building in the community must take the steam service as well as the gas and electric service, consequently many of these steam-heating companies are run in conjunction with the gas and electric company. With the district steam system, the heating of the houses is automatically controlled, the householder being relieved of the firing and ash problem. The cost to the house-

holder is usually from one-third to one-half higher than if he ran his own furnace, the extra cost in lieu of the firing and ash-removal costs. The steam is generated at high efficiency in a large station where the smoke and dust nuisance can be nearly eliminated. Distribution costs are necessarily high, particularly if the city is spread out, and the lengthening mains become more and more costly as the distance increases. Distances of three or four miles are not prohibitive, and many of the smaller industrial plants, hotels, laundries, etc., beside the householders find such a system very attractive. The four district heating plants now operating in Salt Lake City are all in the business district, have a capacity of about 6000 hp., and serve only a small portion of the city. This service could be much further developed, to the mutual advantage of the inhabitants of the city and the steam supply company.

The Householder's Attitude Toward Smoke Abatement

Looking on this problem from the viewpoint of the ordinary citizen, the man in the street so called, the average householder, who owns his six- or eight-room detached house and may be said to be the representative average taxpayer, we find his attitude somewhat disturbing. He sees the locomotive smoke and the industrial chimneys and he does not like it. He sees his neighbors' chimneys also, and when the wind is right the smoke comes in his own windows, and he does not like that. His wife protests that the washing problem becomes worse every day, yet he runs his furnace as usual, has his grate fire for comfort in the evening, pays a man to take his ashes to the sidewalk, and boasts that his total cost for coal and ashes does not exceed $130 per year. He would not buy a better grade of coal at $1 extra per ton. The chances are against his paying $100 for a larger gas connection and the changes to his furnace which might be necessary so that he could use gas and thus avoid smoke. His coal costs him roughly 35 cents per 1,000,000 B.t.u. Substituting gas at present rates he would pay $3.24 for the first 1,000,000 B.t.u. and he sees no economy in that, although he will use the gas stove for some things. With natural gas at 50 cents per 1000 cu. ft. his heat is likely to cost 75 cents per 1,000,000 B.t.u., and he looks askance at the 200 per cent increase. The average citizen is public spirited, but doubling his fuel cost is to him a large price to pay in addition to the 60 per cent increases in his other budget expenses since 1914 which he has had to absorb. District heat at 75 to 90 cents per 1,000,000 B.t.u. would probably interest him, since he might save the cost of his ash removal. If the price was $1.00 to $1.25, a more likely figure, he probably would not consider it. But if he could get smokeless coke or briquets at his present coal price, good salesmanship plus the smoke ordinance would certainly secure his interest, and his public spirit would do the rest.

The industrial use of 400,000 tons may be divided into two portions: the really large plant which can afford to install modern methods of combustion and dust catchers and which are readily amenable to inspection and supervision, and the larger number of smaller installations for which there are three remedies, namely, central-station service, using the smokeless fuel at some additional cost, or combination with other neighboring plants to make an aggregation large enough to be able to afford modern furnaces, good combustion, and dust catchers. Either one of these three remedies would reduce smoke and dust and aid the smoke-prevention service in its work. Modern furnaces and good combustion are greatly aided by the efficient stokers which can now be obtained. These stokers are applicable not alone to the larger sizes of steam boilers, but are now manufactured for small boilers as well. More than 160 stokers are at present installed under the 30,000 hp. of boilers in industrial and heating plants, and about 300 small stokers are in use in domestic heating plants. Installations of this kind are of great use in minimizing the smoke nuisance.

The coal reserves of Utah are estimated by the U. S. Geological Survey to be more than 150 times the yearly coal production of the United States, the work of the last seventy years having depleted these reserves to the extent of less than one-tenth of one per cent. The annual production is not far from 5,000,000 tons, with a value of over $12,500,000. The producing companies, eighteen in number, employ more than 5000 men. The railroad investment in tracks, locomotives, and other equipment serving these mines for coal transportation only is estimated at around $35,000,000. With the allied trades and supply houses it is altogether probable that one-eighth of Utah's population is interested in the well-being of the coal producers, and this fact may explain the protest made against granting the natural-gas pipe-line franchise before the Public Utility Commission.

Conclusions

From the foregoing discussion and its implications we may conclude:

1 That no drastic ordinance or strict enforcement of legal prohibitions of smoke can be of much help in the present circumstances.

2 That no great spending of city tax funds is indicated.

3 That, given the present smoke ordinance and a fund sufficient for vigorous enforcement in a reasonable way, the natural competition between fuels and the economic law of supply and demand will insure a reasonable solution of the problem.

4 One indicated solution under present knowledge is the by-product coke oven supplying domestic coke to householders, coke-oven gas to the gas company, and increasing the use of a most valuable home product, Utah coal. The increase in the number of small household stokers is indicated, and the use of gas in the household will also increase. Competition between supplies and the possibility of mixing coke-oven gas and natural gas will give the gas company a chance to approach nearer the coal price with their services, to the mutual advantage of the company and the citizens of Salt Lake City.

With an assured market for domestic coke and coke-oven gas and the constantly increasing metallurgical industry which is indicated in the reports, the remaining by-products, tar, benzol, and ammonia, should not lack a market; and even if the price obtained should be low, the margin between raw coal and finished products would appear to be above the average. The financing of such a proposition should obviously be handled by the coal industry since it so closely concerns their output and markets, and they should participate in the profits. The city of Salt Lake and its citizens will profit by a smokeless atmosphere, a cheaper gas service, and the extension of the comforts of civilization which follow every major improvement in living conditions.

Discussion

Lewis C. Karrick.[2] This paper, offering an analysis of Salt Lake City's fuel and smoke problem and discussing various fuels and coal-treating processes and other smoke-abatement methods, presents an indefinite and discouraging picture for the Utah coal trade and for those citizens seeking a clear atmosphere. This is not a logical deduction from a thorough analysis of the technical and economic factors peculiar to Utah coals and markets, which favor the complete elimination of all smoke and simultaneous reduction of heating costs. It should have been noted that Utah coals are unique and possess remarkable proper-

[2] Washington, D. C.

ties for producing large yields of rich gas and oils and popular forms of semi-coke not requiring expensive briquetting. The natural-gas enterprise requires for its success that no gas be manufactured for local distribution, and therefore the natural-gas enterprise will operate as a barrier to the success of coal-treating plants by absorbing the revenue due from the sale of by-product gas. It will cost the poor man three times as much to heat with natural gas as by low-priced coal. Furthermore, the very nature of Utah coals permits immediate successful commercial operation of well-known processes only slightly modified in order to supply all the popular semi-coke and gas as rich as natural gas, needed in eliminating all the smoke from Salt Lake City, Ogden, and adjacent towns. These conclusions result largely from studies by myself and associates at the Bureau of Mines Inter-mountain Station, beginning in 1919, assisted by state appropriations made available by the late Governor Simon Bamberger.

J. Billeter.[4] This paper is a real contribution to the solution of Salt Lake City's fuel and smoke problem. Some exception must be taken to the suggestion made that the problem can be largely solved by the use of domestic coke. My experience in the City Smoke Department has shown me that by far the most difficult problem of smoke abatement is that which has to do with residences. The use of fuel for this purpose comes under four distinct headings; namely, cooking ranges, hot-water heaters, grates, and stoves and furnaces.

Coal ranges for cooking have been largely replaced by gas and electricity. At present, coal ranges are found only in the poorer district, where, however, they are used quite extensively. The only coal substitute in the solid state at present is coke. This is unsuitable, for the reason that it is hard to ignite, slow burning, and in short is not at all the kind of fuel the housewife wants to use. Consequently, gas and electricity will have to be depended upon to replace the burning of coal, unless at some future date a more suitable, solid, smokeless fuel (made from Utah coal) is obtainable.

During the winter it is customary to heat the hot water needed by installing water coils in the combustion chamber of the furnace and connecting them with the hot-water tank. This arrangement is quite satisfactory in the average home. During the summer, when furnaces are not used, other provisions must be made. Heaters fired by coal (called monkey stoves) and by gas and by electricity are available. All three types of heaters are used extensively. Here again a solid fuel in the form of coke is not available, for the same reasons given as for cooking ranges. Coal must be replaced by gas and electricity or a better-adapted solid smokeless fuel.

The utility of grate fires consists not so much in the heating of a house as it does in the lending of "atmosphere" to a room and making it "cozy like." The wealthier classes use grate fires considerably more than the middle classes, while the poorer classes do not use them at all, as they cannot afford them. Coke will burn satisfactorily, although in many cases the fire has to be started with coal, and due to the indifference of the public, is replenished by coal. The use of logs in grate fires is so small as to be neglected.

Stoves are used to heat one or two rooms, while furnaces are designed to heat an entire house. Burning coke in stoves has not proved practical, because the combustion chamber is too small for satisfactory coke firing. Wherever possible, furnaces are installed and stoves discarded. A great variety of different furnaces, from anthracite to soft-coal burners, may be found. Over 90 per cent are warm-air furnaces. All sizes of coal are used, from lump to slack coal, with larger coal, however, greatly predominating. Over 250 oil burners, over 100 gas furnaces, and over 250 stokers have been installed in residences. Coke has been used by some for many years with very good results.

The sale of coke has trebled within the last few years. Notwithstanding this fact, the gain in permanent customers has been slow. There are several reasons for this.

Many customers have failed to use coke a sufficient length of time to acquaint themselves with the proper method of firing it. Coke manufacturers have failed to provide a uniform high-grade fuel. At one time they deliver to a customer a satisfactory fuel and perhaps at another time one difficult to burn.

In the morning, substituting a slow-burning coke fire for the convenience of a quick, hot coal fire has not been considered very attractive by the public. Then again, there are those residences that cannot burn coke on account of having furnaces that are too small or chimneys that are inadequate. This applies particularly to a number of old houses.

Petroleum carbon (coke) has been available for a number of years. But it was not until last year that, with the help of an active sales campaign, petroleum carbon was sold in any quantity. For best results it must be used in small sizes. At times it has been coated with oil to make it easier to ignite. This practice is objectionable, because the oil drains off, leaving stains on the basement floor. Petroleum carbon is equally as difficult to ignite as coke, and consequently has the same objections.

Coke has a wide field of useful application, but it also has its limitations. These limitations are believed to be of sufficient magnitude to rule it out as a complete solid-fuel substitute for domestic coal. An easier ignitible, freer, and quicker-burning fuel will have to be provided where coke is not suitable.

The piping in of natural gas from Wyoming will have an important bearing upon the solution of the problem. Through a policy of rendering unusual service and carrying out construction work in a highly efficient manner, the natural-gas people have succeeded in winning the public's good will and confidence. Natural gas will be new in Salt Lake City. Only a few people have lived in localities where natural gas has been used. The extent of the popularity and success of the natural gas remains to be seen.

The availability of natural gas will have a strong tendency to unite the coal producers, but at first it may retard any great fuel development, as the success or failure of the natural gas must first be established. Its popularity will no doubt have a deciding influence in determining the feasibility of building a smokeless fuel plant as also the kind of process that would have to be adopted.

In the meantime the installation of stokers and similar devices will be greatly encouraged.

Lloyd Garrison.[5] The problem of smoke production in Salt Lake City is not essentially different from that found in scores of similar American cities. Smoke production is a factor which has heretofore been considered a necessary evil accompanying industrial development and the universal demand for comfort in the home.

Salt Lake City, while it produces no more smoke than other cities of like size, is so located that the smoke produced is not readily dissipated. Situated within a cove of the mountains, and having very slight air movements during the hours of greatest smoke production, the city finds itself with a rather aggravated condition. In 1919 this condition became so bad that concerted action was taken by the citizenry to abate the nuisance. The results so far obtained from this effort, while still leaving much room for improvement, have been very gratifying.

[4] Engineer of Smoke Abatement, Salt Lake City Corporation, Salt Lake City, Utah. Jun. A.S.M.E.

[5] Consulting Engineer, Utah Coal Producers Association, Salt Lake City, Utah.

A survey of conditions was made by Mr. Osborn Monnett, and a campaign of smoke abatement was based on his findings. Mr. H. W. Clark was placed in charge of the Smoke Department of the city. Mr. Clark directed his efforts chiefly toward reduction of the smoke produced by the larger and medium-sized heating plants and the railroads. Corrections in plant design, instruction of firemen, supervision of new plants, installation of mechanical stokers, and rigid supervision all contributed to the success of Mr. Clark's work. Weather Bureau observations of the number of total smoky hours and total hours of dense smoke show conclusively that a material reduction in the total amount of smoke produced in the city was effected. As a matter of fact, this reduction was 42 per cent during the period from 1920 to 1928, inclusive, although during the same period the number of residences increased 35 per cent.

For several years the Smoke Department was unable to devote much time to residence work because of lack of funds. However, during the past two seasons the Chamber of Commerce has been quite active and has been able to secure funds that have enabled the Smoke Department to give considerable instruction to residence owners in proper firing methods. The public of Salt Lake City is much in sympathy with the efforts being made to abate the smoke nuisance, and the records show a fine spirit of co-operation. Also there have been developed within the last few years automatic stokers adapted to residence plants, and many of these have been installed.

Stokers, oil burners, and gas furnaces all contribute their share toward smoke elimination. However, the writer, while chairman of the Smokeless City Committee of the Chamber of Commerce two years ago, made a careful investigation of the whole situation as shown locally and in other cities, and came to the conclusion that the greater portion of the population will continue to use solid fuel. The reason for this is that coal is materially cheaper than other fuels, no change in equipment is necessary, equipment for its use is cheaper than for other fuels, and it is considerably more reliable than competitive fuels. It therefore became apparent that no solution of the smoke problem locally or elsewhere can be expected until a prepared smokeless solid fuel becomes generally available at a reasonable cost. There are a number of possibilities along this line. Several processes have developed to a point which indicates that a low-temperature coke can be produced economically from Utah coals which are particularly well adapted to low-temperature treatment. Also it may be possible to produce briquets of raw, untreated coal which are smokeless.

The coal industry of Utah is keenly interested in any process or method that will successfully produce a solid, smokeless fuel. Such a development will not only make it possible for the coal industry to render a service to the public for which there is an increasing demand, but will also effect desired economies in operation.

J. D. Roberts.[6] As to the most logical remedy for the deplorable smoke nuisance and fuel problem which exists in the great Salt Lake Valley, it seems that a great deal of time and thought has been given to a possible means of reducing this evil without either curtailing the production of coal or offending the sensibilities of the coal producers. In reality the remedy is at hand in the form of natural gas, which will be turned into the mains of the Utah Gas and Coke Company early in September. This fuel, which has cleared the sky lines of many cities throughout the Southwest and has made them more pleasant places in which to live, will be available to practically all of the inhabitants of Salt Lake City, Ogden, and to those towns lying between Salt Lake City and Ogden and west and south of Salt Lake City, at a price equal to the present market price of coal.

The authors state that the use of natural gas is not absolutely non-smoke producing. This statement is true of any fuel containing carbon, but it is a well-known fact that it is practically impossible to produce any smoke by its use in domestic appliances, and the amount of smoke emitted by industrial users is less than negligible, clear stacks being the rule rather than the exception. A visit to Tulsa, Oklahoma City, Dallas, Fort Worth, Houston, or any other city in the Southwest will demonstrate this fact beyond contradiction.

The writer would like to have a detailed explanation of the authors' comparison of the cost of coal and the equivalent costs of natural gas. Under the proposed schedule of rates, the cost to domestic consumers for 1,000,000 B.t.u. is nothing like 75 cents; rather it is from 55 to 58 cents; and it is neither reasonable nor sound engineering practice to compare natural gas and coal on a B.t.u. basis. The fuel bill of the average citizen will not be doubled in cost as stated by the authors, and it is not seen how the reputed 60 per cent increase in other budget expenses since 1914 has anything to do with the present question.

The authors evidently followed the same line of reasoning when they stated that the domestic fuel bill would be raised from $2,500,000 to $4,000,000 per year. This might be possible if the two fuels were compared strictly on their heating values.

The argument that the Columbia Steel Company, of Provo, by installing an additional battery of 40 coke ovens, could supply Salt Lake City with coke-oven gas is untenable. In the first place, the Columbia Steel Company is not a public utility, and it might be averse to becoming responsible over a long period of time for the domestic fuel supply of Salt Lake City. The amount of coke produced at Provo under any conditions would depend upon the market price for coke and its by-products and also the price of other competitive fuels. In addition, it is most improbable that the Columbia Steel Company could afford to sell coke-oven gas to the Utah Gas and Coke Company at such a price as would amortize the present capital investment in pipe lines, wells, and gas properties, which are now the property of the Western Public Service Corporation, owners of the Utah Gas and Coke Company. The authors mention a price for coke-oven gas of 20 cents per 1000 cu. ft. as a possible price to be obtained in this territory. This price would not nearly satisfy the foregoing requirements, and it is the writer's impression that this price is considerably less than that for which coke-oven gas is sold to the Utah Valley Gas and Coke Company, distributors of coke-oven gas in Provo, Springville, and Spanish Fork, the three towns in the vicinity of the Columbia Steel Company's plant.

Numerous attempts to finance low-temperature carbonization plants in Utah have failed, the reason for which is that, as the authors state, in this country no process has as yet ever been commercially successful.

District steam heating would, as stated by the authors, offer a relief from the smoke nuisance, but evidently distribution costs in the residential districts are prohibitive; otherwise, the present plants, which are owned by very wealthy corporations, would have been expanded long ago.

Natural gas for industrial purposes will be sold at rates competitive with other fuels on the market. The displacement of more than 75 per cent of the coal used for industrial purposes, other than in railroad locomotives, together with the use of natural gas in more than 85 per cent of the homes in Salt Lake City, will be the greatest factor in removing the smoke pall from the Salt Lake Valley that we will ever see.

The authors state that the average householder will look askance at the large increase in his heating bill. I might say

[6] Operating Vice-President, Utah Gas and Coke Co. Mem. A.S.M.E.

that we are now contracting for house heating at the rate of twenty-five per day. This does not appear as though the average householder is greatly worried over an increase in his fuel bill.

It is possibly true that one-eighth of Utah's population is affected to some extent by the production of coal, but their interest in the well-being of the coal producers does not seem to extend to their pocketbooks.

With the coming of natural gas, a smoke-prevention ordinance with "teeth" in it can be drafted and vigorously enforced, since there will then be on the market two smokeless fuels, natural gas and refinery coke, at a price within reach of the average citizen, and there should then be no acceptable excuse for polluting the air with coal smoke. The present smoke ordinance is ineffective, as it is a hard matter to inflict a fine for a smoky chimney when there is no smokeless fuel available in any quantity.

Natural gas is not a new and untried fuel. It will do whatever any other fuel will do and better. Its use as a household fuel and to fire the industrial boilers and factories is general in a number of our larger and most progressive cities. Salt Lake City is not watching an experiment. It is merely awaiting a certainty.

FSP-51-49

The Formation and Thermal Effects of Calcium Sulphate Boiler Scale

By EVERETT P. PARTRIDGE[1] and ALFRED H. WHITE,[2] ANN ARBOR, MICH.

A fundamental study of the manner in which calcium sulphate scale forms upon an evaporative surface, a redetermination of the solubility values for calcium sulphate in the boiler temperature range, and measurements of the rate of formation and heat conductivity of calcium sulphate scales produced in an experimental boiler, are described in abstract in this paper.

Evidence is presented to show that the initial deposition of calcium sulphate scale takes place as the result of the evolution of bubbles, either of dissolved gas or of steam, from an evaporative surface, and that the continued growth of scale is dependent upon the fact that the solubility of calcium sulphate decreases with temperature increase. The work of the authors thus presents a new explanation of the mechanism of initial scale formation, supports Hall's theory of the growth of scale, negates the colloidal theory of scale formation, and offers a fundamental basis for the study of scale-prevention methods. Photomicrographs of the early stages of deposition and growth of calcium sulphate scale are shown, as well as photomicrographs of scales produced under varying conditions.

From the results of their own work and from that of other investigators, the authors present a discussion of the present knowledge concerning calcium sulphate scale. While the effect of scale upon heat utilization in modern boilers is believed to be very slight, calculations based on the heat conductivity of anhydrite scale indicate the importance of preventing overheating of tubes due to the insulating effect of scale deposits within them.

1—THE CRYSTAL FORMS OF CALCIUM SULPHATE AND THEIR SOLUBILITIES

The Forms of Calcium Sulphate

RECENT developments in crystallography[3] recognize the existence of three different forms of calcium sulphate:

Gypsum	$CaSO_4.2H_2O$
Hemihydrate	$CaSO_4.\frac{1}{2}H_2O$
Anhydrite	$CaSO_4$

The form which has frequently been referred to as "soluble anhydrite" has been found to possess the same crystal structure as hemihydrate.[4,5] Substances are known which lose water of hydration without change of crystal form, and hemihydrate apparently belongs to this class. "Soluble anhydrite" may therefore be considered as a partially or completely dehydrated hemihydrate, which, in spite of its loss of water of hydration, possesses the distinctive properties, such as crystal form and solubility,[6] of its parent substance.

It is necessary to consider all three of the forms of calcium sulphate in connection with scale formation, although anhydrite is the only form which is stable in the boiler temperature range. Both gypsum and hemihydrate are found in scale produced during short-time tests (up to 48 hours) with solutions boiling under atmospheric pressure. Hemihydrate alone is present in scale produced from solutions boiling under a gage pressure of 25 lb. per sq. in. during tests of similar duration. The occurrence of these forms of calcium sulphate in scale is undoubted, but experiment has shown that they must exist as metastable phases, since gypsum crystals in contact with water at the atmospheric boiling point are gradually replaced by crystals of anhydrite.[5]

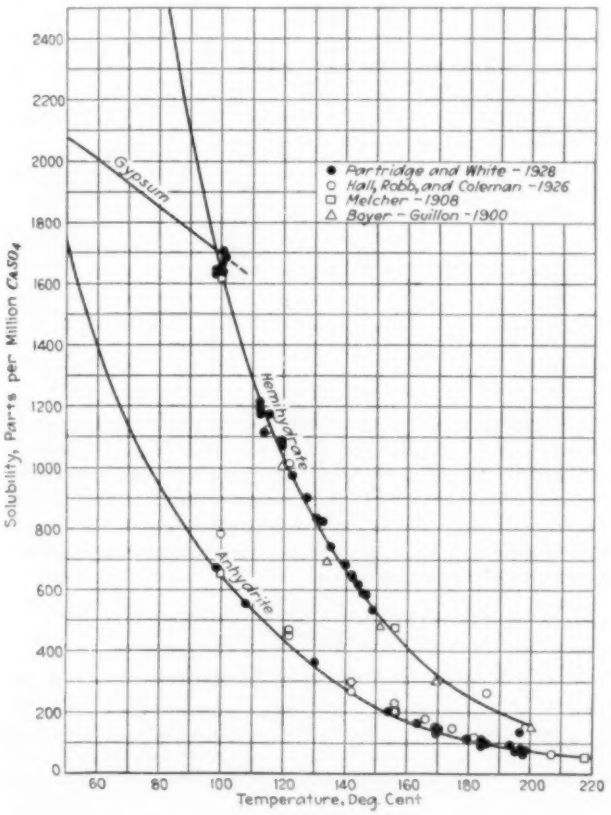

FIG. 1 SOLUBILITIES OF CALCIUM SULPHATE

All three forms of calcium sulphate give scale deposits which are essentially similar in being crystalline, hard, compact, and continuous. The differentiation between the three forms can be made only by crystallographic methods or X-ray analysis.

---

The Solubilities of the Forms of Calcium Sulphate

The solubility values for calcium sulphate will be considered in this paper only in the range above the atmospheric boiling point. Gypsum goes over readily to hemihydrate above 98 deg. cent. or 208 deg. fahr. Although hemihydrate is metastable with respect to anhydrite, it apparently persists over considerable periods of time in contact with water at temperatures from 100 to 135 deg. cent. or 212 to 275 deg. fahr. The solubility curve of hemihydrate must therefore be considered as well as that of anhydrite.

The solubilities of hemihydrate or of anhydrite have been determined by Boyer-Guillon;[7] Melcher;[8] Hall, Robb, and Coleman;[9] and the authors.[10] An early determination by Tilden and Shenstone may be disregarded, although credit for pioneer work belongs to these investigators. Fig. 1 shows the solubility curves determined by the points of the four more recent series of data. In plotting the anhydrite curve, only the minimum individual values obtained by Hall, Robb, and Coleman have been used, since at the lower temperatures their other data fall considerably above the values obtained by Melcher and by the authors. Table 1 gives values at intervals of 10 deg. cent. taken from a large-scale plot of Fig. 1.

TABLE 1 SOLUBILITY OF HEMIHYDRATE AND ANHYDRITE BETWEEN 100 AND 220 DEG. CENT.

(The values in this table are taken from curves determined by the data of Boyer-Guillon;[7] Melcher;[8] Hall, Robb, and Coleman;[9] and the authors.[10])

Temperature		Solubility expressed as parts $CaSO_4$ per million parts solution	
Deg. cent.	Deg. fahr.	Hemihydrate	Anhydrite
100	212	1645	650
110	230	1290	535
120	248	1030	435
130	266	830	350
140	284	665	280
150	302	530	222
160	320	415	176
170	338	325	140
180	356	255	112
190	374	205	92
200	392	165	76
210	410	..	64
220	428	..	55

The significance of the negative slope of the solubility curves of calcium sulphate with respect to the formation of anhydrite scale upon boiler evaporative surfaces has been pointed out by Hall and his co-workers.[11,12,13] In a subsequent section of this paper an attempt will be made to correlate quantitatively the rates of scale formation at various temperatures with the corresponding solubility-curve slopes.

2—THE MECHANISM OF FORMATION OF CALCIUM SULPHATE SCALE

Theories of Scale Formation

Two theories of scale formation have been described in the last five years. The first of these may be called the theory of colloidal precipitation; the second, the theory of deposition at the hot surface.

The theory of colloidal precipitation,[14,15] as described by French and by E. M. Partridge, holds that scale is formed initially as a fine dispersion of solid particles throughout a boiler solution as the latter attains saturation. These particles, suspended in the moving currents of boiler water, strike at random upon the evaporative surfaces, become accidentally attached to them, and gradually form a hard, crystalline mass. Up to the present time

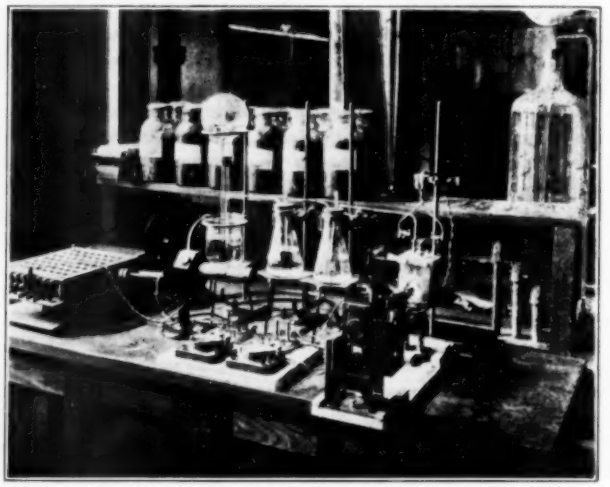

Fig. 2 Apparatus for Photomicrographic Study of Mechanism of Scale Formation

no experimental evidence has been adduced in favor of this theory.

The theory of deposition on the hot surface, advanced by Hall and his co-workers,[11,12,13] is almost exactly opposed to the previously described theory. According to Hall, scale forms only at a surface at which heat transfer is taking place, and its formation is dependent upon the fact that the film of fluid in contact with a heated metal surface must actually be at a somewhat higher temperature than the body of the boiler solution. If the body of solution is, however, saturated with calcium sulphate, such an increase in temperature at the hot surface must cause the deposition of the excess solid material directly at this surface, rather than in the body of solution. Hall has provided experimental verification of the soundness of his theory, both on a laboratory and on a plant scale.

Experimental Work

Reference has previously been made to the fact that the authors have produced scale containing either gypsum and hemihydrate, hemihydrate, or anhydrite, and that in each case the properties of the different scale samples were markedly similar. This similarity makes it possible to study the mechanism of scale formation at the atmospheric boiling point, where the rate of formation is rapid, and a metastable deposit of gypsum is produced, with a good degree of assurance that the scaling process is fundamentally the same as that which takes place in a boiler which is depositing anhydrite scale under modern operating conditions of temperature and pressure.

was made by the authors, using solutions of calcium sulphate boiling under atmospheric pressure. The apparatus is shown in Fig. 2. The principle of the metallographic microscope was utilized by making the evaporative surface upon which the scale was to be formed a highly polished deposit of chromium plate upon a brass base. This metallic mirror formed the front face of a brass box containing an electrical-resistance heating unit. The brass box was immersed in calcium sulphate solution in a brass cell having a glass window on one side, through which a microscope was focused on the mirror surface on which scale formation was expected. Light was supplied by an arc lamp, the beam from which was reflected upon the mirror surface and in turn reflected back through the microscope. A small moving-picture camera adjusted to take single instantaneous exposures and an observation ocular were attached to the microscope so that the process of scale formation could be photographed without interruption of visual observation.

Scale formation was first studied with calcium sulphate solutions saturated at room temperature and containing dissolved air. When these were used it was found that the heat from the evaporative surface caused small bubbles of air to come out of solution on the metal surface before the boiling point was reached. As each of these bubbles grew, it was finally detached from the surface by its own buoyancy, disclosing a ring of crystals which marked the line at which the solid surface, the solution, and the gas bubble had been in contact. The appearance of such a ring, immediately after the departure of the bubble under which it was formed, is shown in Fig. 3(*b*). The small crystals deposited in each ring as the result of bubble evolution grew rapidly, as shown in (*c*) and (*d*), Fig. 3, forming an interlocking network of needle crystals which rapidly obscured the original rings.

In order that the normal course of scale formation might be more closely reproduced in the laboratory, the procedure was then changed to the following. The apparatus was filled initially with distilled water, heat was supplied as before, and the water in the cell was boiled continuously with a make-up of calcium sulphate solution which was deaerated and heated to the boiling point in a series of flasks, vented to the atmosphere, through which it passed slowly on its way to the cell. This deaerating system appears in Fig. 2, together with the automatic-feed solution reservoir.

Starting with distilled water in the cell, between two and three hours were required for the cell solution to arrive at saturation. The first traces of crystal deposition from the initially unsaturated and well-deaerated solutions were, however, strikingly similar to those previously obtained from the evolution of bubbles of dissolved gas. Very fine rings first appeared on the surface, as in (*a*), Fig. 4, and from these rings small needle crystals grew into the solution as before. This growth is shown in the successive pictures in Fig. 4.

Since the extremely low concentration of dissolved gases in the cell solution could not account for the ring deposits produced from the initially unsaturated solutions, it seemed probable that these rings were produced by the evolution of steam bubbles rather than gas bubbles, and that the fundamental mechanism by which calcium sulphate formed scale had been observed.

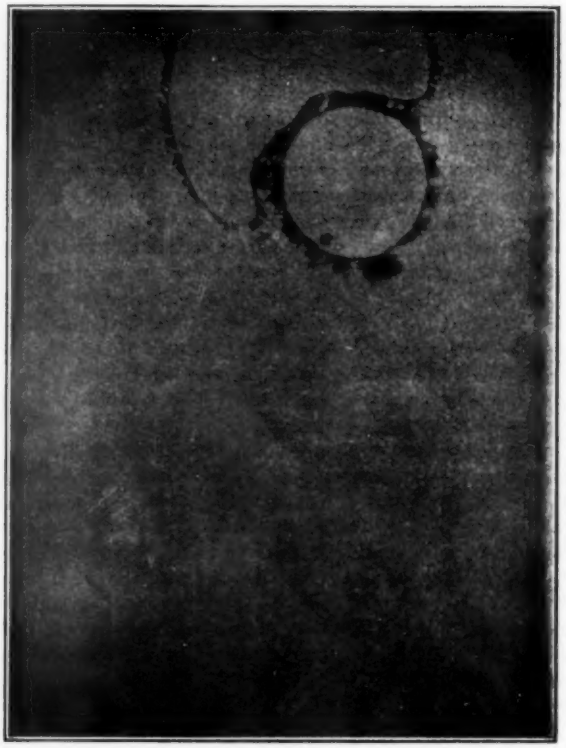
Some experiments were also made with the evolution of dissolved-gas bubbles from calcium sulphate solutions which were made up to a concentration slightly below the saturation value. It was found that crystal rings were formed by bubble evolution, but that immediately upon the departure of each bubble the crystal ring deposited by it commenced to redissolve, disappearing completely within a few seconds.

A New Theory of Calcium Sulphate Scale Formation

The work of the authors gives the first experimental evidence of the mechanism of initial scale formation, which is shown to depend upon the evolution of bubbles from an evaporative surface. This surface is necessarily hotter than the body of solution, and tends to superheat the film of solution next to it, with the result that small areas of the film suddenly vaporize, forming minute steam bubbles which are actually in contact with the heated surface. The line of contact between each bubble and the surface is ring-shaped. Outside of each ring the heated surface is in contact with the normal fluid film, but within each ring the surface is in contact with dry vapor. The resistance to heat flow of this vapor is much greater than that of the normal film of solution, hence the surface tends to overheat slightly beneath each bubble. This local overheating causes evaporation to take place from the very thin layer of solution surrounding the dry surface. As evaporation into the bubble continues, the latter grows and is finally detached from the metal surface by its own buoyancy, the solution closes over the dry spot on the surface, and the normal fluid film is again established.

When such a process of bubble evolution takes place at a surface in contact with a solution saturated with calcium sulphate, the fluid film at the heated surface must be supersaturated by the increase in temperature at that point. As the bubble forms, the thin layer of this supersaturated solution at the line of contact between the bubble and the surface is subjected to increased evaporation, and is forced to deposit minute crystals in close contact with the metal surface. From the time of their first deposition, these crystals are always in contact with a solution supersaturated with calcium sulphate, at first by evaporation of water into the bubble, and, after the departure of the bubble, by the return of the normal fluid film. They thus tend to grow continuously as long as heat is being transferred across the evaporative surface.

The continued growth of the crystals of calcium sulphate after their initial deposition confirms the theory of scale formation stated by Hall, while all of the experimental evidence contradicts the colloidal theory of scale formation. In addition, the new theory advanced by the authors allows a logical explanation of the formation of the thin calcium carbonate or calcium phosphate scales which are customarily formed upon the evaporative surfaces of boilers using soda ash or sodium phosphate for internal conditioning. Calcium carbonate is known to increase in solubility with increase in temperature, and calcium phosphate is believed to have a similar characteristic; hence, according to Hall's theory, these substances should not form scale on hot surfaces, since they would be more soluble in the fluid film at the hot surface than in the body of the boiler solution. A characteristic property of these scales is the fact that they do not appear to increase in thickness over long periods of time. From consideration of the results obtained with the evolution of gas bubbles from slightly undersaturated solutions, this anomalous scale formation can be explained as the equilibrium between two opposed actions. On the one hand, the evolution of steam bubbles at the evaporative surface deposits small crystals at the minute solid-liquid-vapor interfaces formed under the bubbles, while on the other hand, the condition of undersaturation produced in the fluid film by its increase in temperature over the body of the boiler solution is continually tending to cause these minute deposited crystals to redissolve.



3—THE THERMAL EFFECTS AND RATE OF FORMATION OF CALCIUM SULPHATE SCALE

Previous Investigations

Very little quantitative information is available concerning the resistance to heat flow across boiler heating surfaces caused by the formation of scale on these surfaces. Several series of experi-

ments were made at the University of Illinois between 1898 and 1905,[16] which indicated decreases, varying up to 15 per cent, in the rate of heat transfer across locomotive boiler tubes which had formed scale in service, and had then been removed and tested under laboratory conditions. The scale formation on these tubes had taken place under widely varying conditions, and the data obtained are dependent upon too many unevaluated factors to be used as conclusive evidence at the present time. One hand-picked excerpt[17] from these data indicates the results much less accurately than it does the bias of the person who compiled it. Individual determinations in the original data vary widely, due both to experimental error and to great variation in the physical structure and composition of the scales tested.

In the original calculations from the test data, arithmetical mean average temperature drops were used. The authors have recalculated the data, using logarithmic mean temperature drops, and have averaged the results obtained for all scales of a given thickness, without any attempt at consideration of other factors or weighting of individual determinations. The results are given in Table 2, which expresses the decrease in overall conductivity of scaled 2-in. boiler tubes expressed as a percentage of the overall conductivity of clean tubes, against the thickness of the scale deposit on the tubes.

TABLE 2 DECREASE IN OVERALL CONDUCTIVITY OF SCALED BOILER TUBES AS A FUNCTION OF SCALE THICKNESS

(Recalculated, using logarithmic mean temperature drops, from the data of Schmidt and Snodgrass, University of Illinois Engineering Experiment Station Bulletin No. 11. Determinations for different scales of the same thickness have been averaged together without attempt at an evaluation of the factors of scale composition and structure and without weighting of individual values.)

0.13	6.6[a]	1	2

[a] Probably poor values, due to small number of scales tested.

Comparative tests on a locomotive, also reported by Schmidt and Snodgrass, showed a decrease in heat utilization of 9.55 per cent when the principal heating surfaces were covered with a scale averaging 0.05 in. in thickness. These investigators refer to earlier railroad operating tests which indicated decreases in fuel utilization of from 11 per cent to 22 per cent for scaled locomotives as compared with similar ones run with clean boilers. These road tests are, however, to be given little weight as quantitative determinations.

The high values for heat loss due to scale reported in some of the individual tests at the University of Illinois have naturally been emphasized by the proponents of feedwater-treatment systems.[18] Croft, also of the University of Illinois, has recently protested against misinterpretation of the older data, and has published the results of a more accurate test.[19] He found, by heat-transfer tests on a 4-in. No. 9 B.w.g. boiler tube operated at 118 lb. per sq. in. gage pressure, that 0.1-in. and 0.2-in. thicknesses of scale caused respective losses in heat utilization of 1.67 and 2.99 per cent at an operating rating of 90 per cent, and losses of 3.83 and 5.98 per cent at a rating of 225 per cent.

The most complete experimental data on the effect of scale on heat utilization are those published by Reutlinger.[20] This work was done under the supervision of Eberle, who was probably the first investigator to show that figures for heat losses due to scale had been greatly exaggerated. In 1909 he was saying:[21]

> From the results of the experiments it is to be concluded that a scale deposit averaging 5.5 mm. (0.22 in.) in thickness and of average heat conductivity influences the heat utilization in a boiler but very little, so that the determination of this influence by comparative boiler tests in a reliable manner is not possible. As long as the average scale thickness of 5 mm. is not exceeded, which can probably be regarded as the rule for all regulated operation, the decrease in heat utilization due to the scale deposit is not likely to exceed 5 per cent, even with a scale of very low conductivity; with scale deposits of this thickness and medium conductivity this influence is likely to amount to only 2 to 3 per cent.

The work of Eberle and Reutlinger on heat utilization losses due to scale has been quoted by Hempel,[22] but has not been widely disseminated.

Hellemans,[23] more recently, states that both theoretical calculations and actual comparative boiler tests show that the heat losses claimed to be due to scale are exaggerated. In an actual boiler test the removal of scale varying in thickness from 0.75 to 12.0 mm. (0.03 to 0.47 in.) had no appreciable effect on the efficiency of heat utilization.

Thus far, attention has been directed to the effect of scale upon heat utilization. While it is conceivable that this effect may have been important in early types of boilers, it appears that it is very small in boilers of modern design. In considering the heat effects of scale in the latter, emphasis must be shifted from the viewpoint of heat utilization to that of overheating of the boiler metal. It is precisely the heat-transfer surfaces exposed to the most severe conditions on which calcium sulphate or silicate scales will form most rapidly. While a scale deposit in a front-row boiler tube can have no effect upon the absorption of radiant energy by the metal of the tube, it does offer, as it grows in thickness, a steadily increasing resistance to the flow of heat from the tube metal to the liquid within the tube. As a consequence, the temperature of the tube metal must increase in order to drive through the increasing resistance the constant flow of heat it is receiving by radiation. Not a very great amount of scale is necessary to raise the tube temperature to a point at which the steel will fail.

It is interesting to note that, while the conclusions of Eberle and of Reutlinger concerning the slight effect of scale upon heat utilization have not been quoted in this country, the values for increase in heating surface temperature due to scale, taken from Reutlinger's same extensive article, are used quite generally.[24,25] These latter values and a separate determination by Croft will be discussed in connection with the results of experiments by the present authors, which will now be reported. This latter work was intended to determine the actual thermal conductivities of calcium sulphate scales produced upon an evaporative surface, with accurate measurement of the temperature of the surface

itself and of the temperature drop from the tube surface to the solution. This work was done in an experimental boiler at several different pressures between atmospheric pressure and 150 lb. per sq. in. gage pressure, and afforded data not only for determinations of conductivity and tube-surface-to-solution temperature drops, but also for the testing of a theoretical expression for the rate of scale formation as a function of the slope of the solubility curve of the scaling substance. This relation will be described in a subsequent section of this paper.

Experimental Work on Heat Conductivity of Calcium Sulphate Scale

Scale-formation tests were conducted in an experimental boiler unit, shown in Fig. 5, in which it was possible to maintain a constant rate of heat transfer across a small tube surface which was in contact with calcium sulphate solution. The temperatures of the tube surface and of the solution were measured by separate thermocouples, and the difference in temperature was also obtained directly by a differential connection. Accuracy in the measurement of the tube surface temperature was obtained by the use of a thermo element of the plated-surface type.[26]

Scale was formed during runs varying in length from 12 to 200 hours. The pressures used were atmospheric, and 10, 25, 50, 100, and 150 lb. gage. The rate of heat transfer was maintained constant during all runs at a value of 18,720 B.t.u. per sq. ft. per hour, by means of constant electrical power input to the tube used for scale formation, and by the use of an air thermostat in which the boiler was suspended. At the end of a run, whenever scale had been formed in an appreciable continuous deposit, the thickness of the scale and the weight deposited per unit of area were measured.

At the beginning of a run the average temperature drop from the tube surface to the solution was found to be 5 deg. cent. or 9 deg. fahr. This temperature difference was due entirely to the resistance to heat flow of the fluid film at the tube surface. The gradual formation of scale upon the tube surface interposed an additional increasing resistance to heat flow which resulted in an increased value for the tube-surface-to-solution temperature drop. As scale formed, the surface in contact with the solution necessarily became rougher than the original smooth metal surface, and consequently the thickness of the fluid film and its resistance to heat flow probably increased somewhat. This would result in a corresponding increase in the temperature drop across the fluid film, but since it was not possible to determine experimentally the amount of this change, and since its magnitude in most cases must have been small, it has been assumed that the temperature drop across the fluid film remained constant at its original value. By subtracting this value found at the beginning of a run with a clean tube from the temperature-drop value found at the end of a run, the temperature drop due to the scale deposit was obtained. From this last value, and from the measured thickness of scale and the known rate of heat transfer, the heat conductivity of the scale was calculated. The data are shown in Table 3 for the six samples of scale which had a measurable uniform thickness.

The last column of Table 3, which gives the heat-conductivity coefficient for the various samples of scale in terms of the customary units as B.t.u. per hour per square foot per degree fahrenheit per foot thickness of material, shows values ranging from 1 to 2 for five of the six samples. The apparent high value of the scale formed at 10 lb. pressure is due to the fact that overall thickness was measured. The unusual structure of this scale, together with the structure of other typical samples, is shown in the photomicrographs of Fig. 6. While the total thickness of the 10-lb. scale was 0.173 in., the thickness of the continuous layer was only 0.028 in., the remainder consisting of individual, unconnected needle crystals growing out radially from the surface. If the layer of solid material is assumed to be the only resistance to heat flow, the value of the heat-conductivity coefficient for this layer comes out as 0.95. From this consideration, which places the value for the 10-lb. scale in line with the others, it seems probable that the actual coefficient for calcium sulphate scales lies between 1 and 2. Within the experimental error of the determinations, the variation between the different forms of calcium sulphate is not distinguishable.

TABLE 3 HEAT CONDUCTIVITY OF CALCIUM SULPHATE SCALES PRODUCED IN EXPERIMENTAL BOILER

Gage pressure, lb. per sq. in.	Duration of run, hr.	Thickness of scale, in.	Temperature drop through deg. scale, fahr.	Heat-conductivity coefficient, B.t.u. per hr. per sq. ft. per deg. fahr. per ft.
0	12	0.021	31.0	1.06
10	48	0.173[a]	46.0	5.87[a]
25	48	0.056	50.0	1.75
25	48	0.044	47.0	1.46
50	48	0.019	14.4	2.06
150	200	0.0032	5.4	0.93

[a] Note unusual structure of scale, shown in Fig. 6. Although the total thickness of scale is 0.173 in., less than a quarter of this is solid material, the remainder consisting of needle crystals projecting into the solution. If the thickness of the solid deposit is considered alone, the heat-conductivity coefficient becomes 0.95.

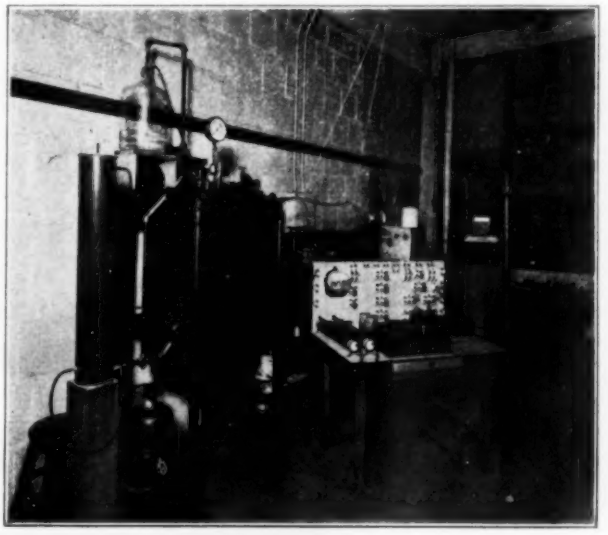

Fig. 5 Experimental Boiler Unit

Discussion of Heat Conductivity of Scale

Reutlinger's data on the conductivity of scale[20] were obtained in an apparatus with a horizontal cast-iron heating surface, and show very high temperature drops from this heating surface, when perfectly clean, to the body of the boiling solution. Thus at a heat-transfer rate of 10,850 B.t.u. per sq. ft. per hour, the temperature drop from heating surface to solution is 30 deg. cent. or 54 deg. fahr. The present authors, using a vertical tube with a polished nickel surface as their heating unit, found a tube-surface-to-solution temperature drop of only 5 deg. cent. or 9 deg. fahr. for a heat-transfer rate of 18,720 B.t.u. per sq. ft. per hour. In the latter case, convection past the heated surface was undoubtedly much more rapid, and the fluid film at the surface was much thinner than in Reutlinger's apparatus, conditions which account for some of the discrepancy between the figures.

The actual temperature drops through Reutlinger's two calcium sulphate scales are quite comparable with the values obtained by

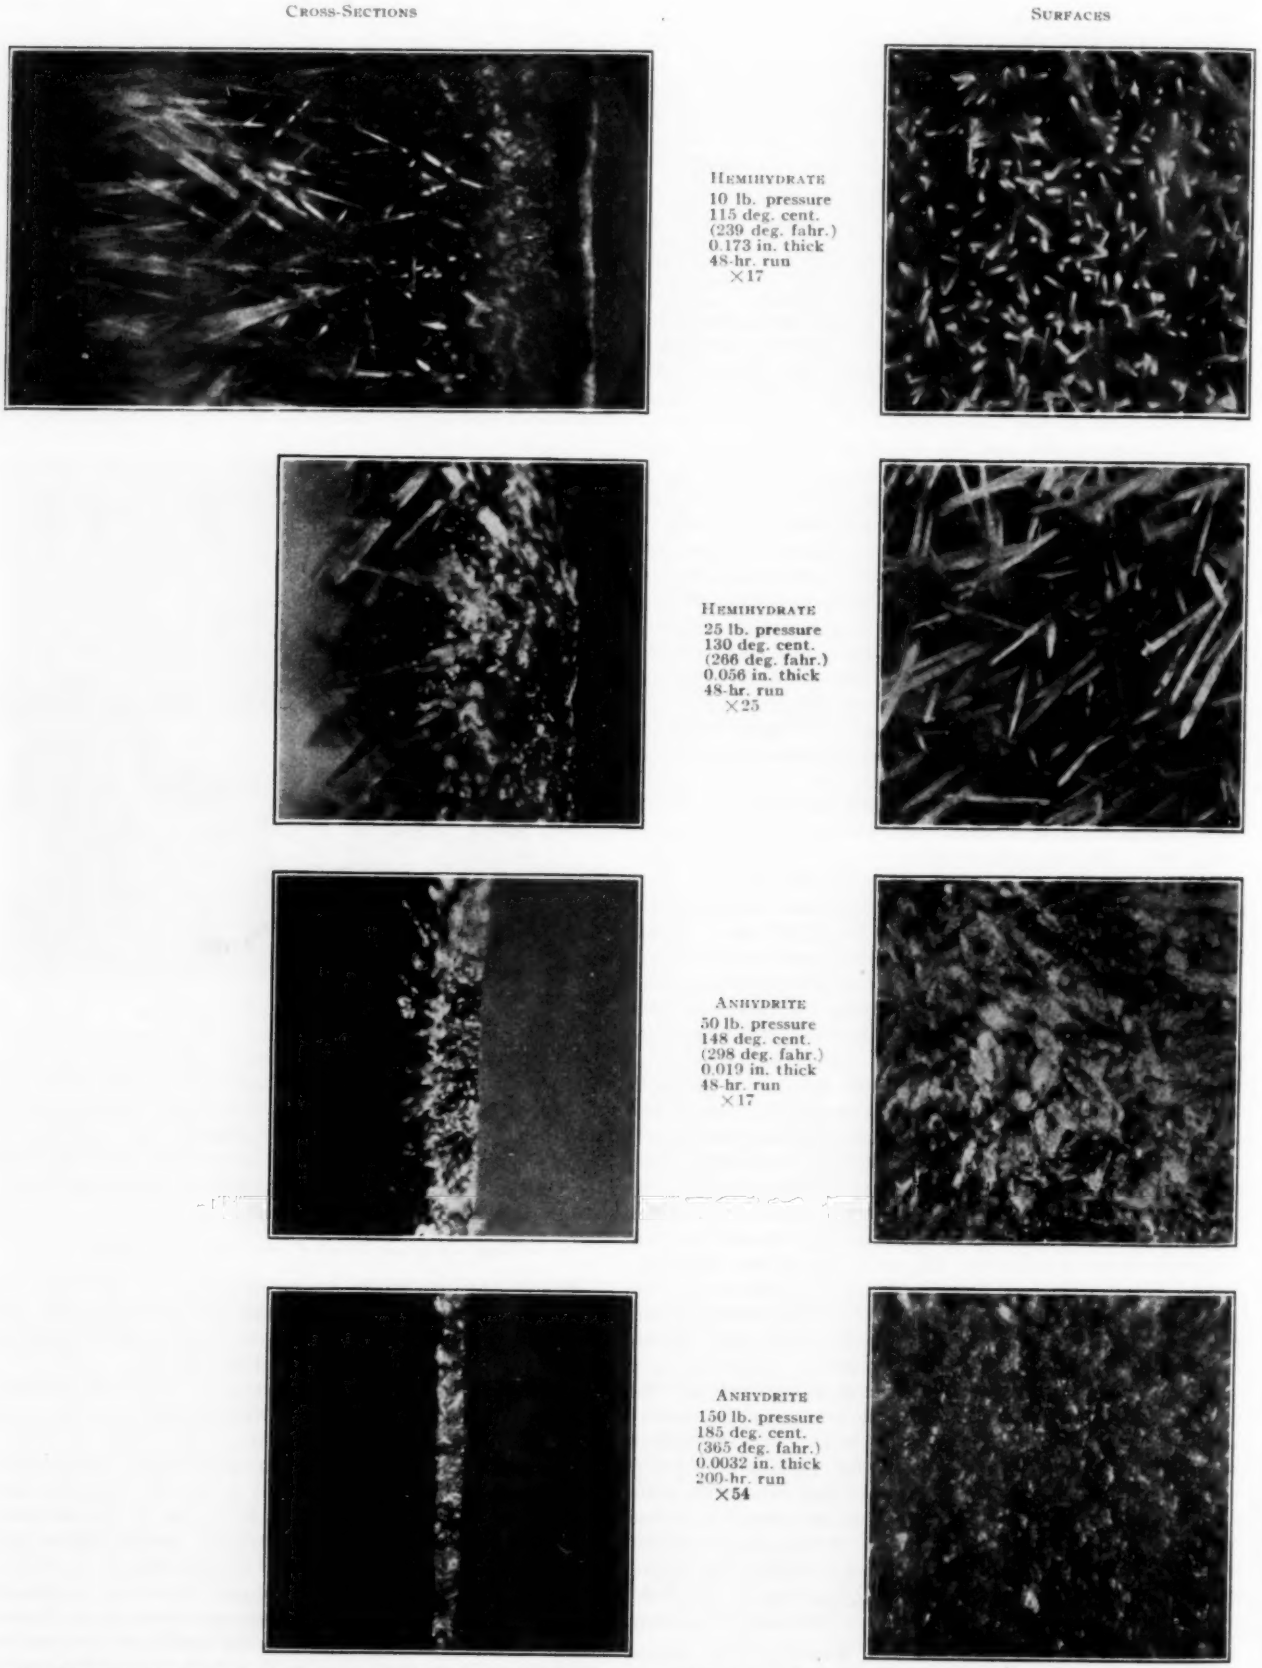

Fig. 6 Comparison of Cross-Sectional and Surface Appearance of Scales Produced at Various Pressures in Experimental Boiler

the present authors, the heat-conductivity coefficients coming out respectively as 1.27 and 1.94 B.t.u. per sq. ft. per hour per deg. fahr. per ft. thickness of material.

The single determination by Croft,[19] previously referred to, showed a temperature drop of 20.6 deg. cent. or 37 deg. fahr. from the clean tube surface to the solution when operated at 90 per cent of rating, or a heat-transfer rate of 3013 B.t.u. per sq. ft. per hour. This temperature drop across the fluid film is even higher, relative to the rate of heat transfer, than those reported by Reutlinger, and seems somewhat excessive to the present authors. A scale deposit of 0.1 in. thickness on the tube used by Croft increased the tube temperature 8.3 deg. cent. or 15 deg. fahr. The conductivity, as calculated by Croft, is equal to 1.75 B.t.u. per sq. ft. per hour per deg. fahr. per ft. thickness of material, a value well in line with those of Reutlinger and of the present authors. All of the values reported fall between 1 and 2, while the average is 1.46.

The front-row tubes and water walls of boilers at the present time are subjected to very severe radiation. It is probable that a large percentage of the heat transferred across these surfaces is received by direct radiation, a condition which would tend to maintain a constant rate of heat input to the metal of the tubes, regardless of the increasing resistance to the conduction of heat away from the metal imposed by a layer of scale depositing within the tubes. If this assumption of constant rate of heat input is made, and the value of the heat-conductivity coefficient for anhydrite scale is taken as 1.5, it follows that a scale deposit of 0.01 in. will cause an increase in the metal temperature beneath the scale of approximately 3.1 deg. cent. or 5.6 deg. fahr. for each 10,000 B.t.u. per sq. ft. per hour passing across the metal surface. For a boiler operating at a heat-transfer rate of 70,000 B.t.u. per sq. ft. per hour across the front-row tubes, each 0.01 in. of calcium sulphate scale would cause an increase in the tube-surface temperature of approximately 22 deg. cent. or 39 deg. fahr.

At 150 lb. per sq. in. gage pressure, the boiler-water temperature is 185 deg. cent. or 365 deg. fahr. Anhydrite scale 0.10 in. thick would, from these figures, cause a tube-metal temperature of 401 deg. cent. or 753 deg. fahr. for the heat-transfer rate cited. From the results of experiments with the formation of scale at 150 lb. pressure in the laboratory boiler, it seems probable that a scale 0.10 in. thick could be formed in 70 days at the heat-transfer rate of 70,000 B.t.u. per sq. ft. per hour, provided the boiler water were continuously saturated with respect to calcium sulphate.

At present there is a double tendency toward the use of higher pressures and of higher ratings for steam boilers. The first tendency narrows the limits for the safe increase of tube temperature over boiler-water temperature, and at the same time increases the probable penalty for tube failure. Its effect in decreasing the rate of scale formation is not known above 200 lb. gage pressure, while the second tendency toward higher ratings tends to increase the rate of scale formation. The net result is that it becomes increasingly important to prevent scale formation as boiler pressures and temperatures are increased. For example, 0.07 in. of scale at 600 lb. pressure, and 0.04 in. of scale at 1500 lb. pressure, will each cause an actual tube temperature equivalent to that caused by 0.10 in. of scale at 150 lb. pressure, the rate of heat transfer being the same as given, 70,000 B.t.u. per sq. ft. per hour, in all cases.

In the preceding calculations the temperature drop across the fluid film has been neglected. While the work of Reutlinger and of Croft indicates that its value may be appreciable, the experiments of the present authors suggest the great influence which convection and surface conditions may have upon its magnitude. By neglecting it in the calculations, the tube-temperature-increase figures are made very conservative. In the calculations the additional assumption has been made that the heat conductivity of anhydrite scale is constant over the temperature range involved. The rate of heat transfer quoted, 70,000 B.t.u. per sq. ft. per hour, is a conservative estimate for the condition in tubes exposed to severe radiation in modern boiler settings.[37]

These estimates as made indicate the part that scale may play in causing the failure of boiler tubes exposed to radiant heat. Another factor which may enter into the failure of tubes from overheating is the possible complete evaporation of water within these tubes, a condition which would result in a tremendous increase in the resistance to heat flow from the tube metal. That such a condition ever exists is not definitely known. As long as the tubes are wetted by a foam, overheating will not occur; on the other hand, only a brief period of complete vaporization would be necessary to cause failure.

Rate of Formation of Calcium Sulphate Scales

During the course of the scale-formation tests it was discovered that the rate of formation was much lower at the higher pressures. It did not seem probable that this effect was actually the result of variation in pressure, therefore an explanation was sought in the corresponding variation in temperature, and in the effect of this variation upon the solubility of calcium sulphate.

Since it was not known at the time which of the forms of calcum sulphate might be present in the scale samples from the various runs, refractive index measurements and X-ray determinations of crystal structure were made on portions of these samples for purposes of identification. These tests showed the results given in Table 4.

TABLE 4 CRYSTAL FORMS OF CALCIUM SULPHATE PRESENT IN SCALE FORMED AT VARIOUS PRESSURES IN EXPERIMENTAL BOILER

Gage pressure, lb. per sq. in.	Temperature		Duration of run, hr.	Crystal form of calcium sulphate
	Deg. cent.	Deg. fahr.		
0	100	212	12	Gypsum and hemihydrate
10	115	239	48	Hemihydrate
25	130	266	48	Hemihydrate
50	148	298	48	Anhydrite
100	170	338	48	Anhydrite
150	185	365	200	Anhydrite

The process of scale formation was then considered from a theoretical standpoint. Given a solid surface across which heat is being continuously transferred to a solution saturated with respect to calcium sulphate, and given an initial deposit of crystals upon this surface due to bubble evolution or to incomplete removal of old scale, further growth of these crystals depends upon the degree of supersaturation produced in the fluid film at the surface by the transfer of heat across it. This degree of supersaturation depends upon the change of solubility of calcium sulphate with the change in temperature from that of the body of solution to that of the somewhat hotter fluid film. For a given rate of heat transfer and constant surface conditions of steam evolution and convection, this temperature gradient would be the same for all temperatures at which the boiler was operated, but the change in solubility over this temperature gradient would vary greatly with the actual solution temperature. For example, by referring to the solubility curve of Fig. 1, it is seen that at 110 deg. cent. or 239 deg. fahr., at which temperature hemihydrate scale is formed, the change in solubility with a 5 deg. cent. or 9 deg. fahr. increase in solution temperature is —140 parts per million, while at 185 deg. cent. or 365 deg. fahr., corresponding to a pressure of 150 lb. gage, under which conditions anhydrite is the form of calcium sulphate produced in scale, the change in solubility for the same increase in temperature is only —12 parts per million.

[37] The Detroit Edison Company. Private communication to the authors.

It is difficult to conceive of experimental refinements which would allow the measurement of the actual temperature gradient from the very thin fluid film at the hot surface to the body of solution, but without knowledge of this actual value it is impossible to state exactly the degree of supersaturation produced in this film at any given temperature of operation. A close approximation may be obtained, however, by considering the degrees of supersaturation produced at different temperatures, but at the same rate of heat transfer, to be proportional to the negative values of the slopes of the solubility curve at these temperatures, using in each case the solubility curve for the form of calcium sulphate produced as scale. The degree of supersaturation produced in the fluid film may, however, be considered as the driving force in the continued growth of scale from the initial nuclei. On this basis the theoretical statement may be made that the rate of scale formation is a direct negative function of the slope of the solubility curve of the scaling substance. If the following notation is adopted: namely,

D = quantity of scale formed
S = solubility of scaling substance
T = temperature
t = time, and
c = a constant,

then the foregoing relation may be expressed mathematically as

$$\frac{dD}{dt} = -c\frac{dS}{dT}$$

This equation was tested with the data obtained from the work with the experimental boiler. Table 5 presents the data. The slopes of the solubility curves were obtained by graphical differentiation of the solubility data of Table 1. The rate of scale formation is expressed in three ways: as the slope of the line representing the increase in temperature difference between the tube surface and solution, or in other words, as the rate at which the resistance to heat flow increased; as the weight of scale, corrected to $CaSO_4$, deposited per square foot of surface per day; and as the thickness of scale deposited per day.

TABLE 5 CORRELATION OF RATE OF SCALE FORMATION WITH SLOPE OF SOLUBILITY CURVE AT VARIOUS TEMPERATURES

(Rate of heat transfer, 18,720 B.t.u. per sq. ft. per hr.)

Gage pressure, lb. per sq. in.	Duration of run, hr.	Solubility slope, p.p.m. per deg. cent.	Rate of scale formation: Slope of temp. drop, deg. cent. per hr.	Rate of scale formation: Weight of scale, lb. per sq. ft. per day	Rate of scale formation: Thickness of scale, in. per day
0	12	−34.0 (H)[1]	1.17	....	0.042
10	48	−27.0 (H)	0.71	0.320	0.086

[1] (H) Hemihydrate; [2] (A) Anhydrite.

Due to the difference in structure of scales produced at different temperatures, referred to previously, and shown in photomicrographs in Fig. 6, the thickness of the scales from the experimental boiler is not a good criterion of the rate of scale formation for comparison of values over a wide range of temperatures. When the figures for the slope of the temperature-drop-increase lines from the scale-forming runs at different temperatures are plotted against the values for the slope of the solubility curve at these temperatures, a straight-line relationship is indicated, as shown in Fig. 7. Similarly, when the rate of scale formation as pounds per square foot per day is plotted against the slope of the solubility curve, a straight line probably expresses the best relation, although the fact that the value at atmospheric pressure was not determined makes this relation less conclusive than the previous one. Like points in each set of data fall in similar positions, however, indicating that the slope of the temperature-drop increase is a fair measure of the actual rate of scale formation.

The probable error in the location of points on the rate-of-scale-formation axis in Fig. 7 is rather large, since the scale forming on the tubes was found to break off occasionally during a run. On this account the values for rate of scale formation cannot be taken as exactly quantitative. The data do, however, indicate the probability of a direct proportionality between the rate of scale formation and the negative of the solubility slope.

4—SUMMARY AND DISCUSSION OF SCALE FORMATION

On the basis of the work of other investigators and of that reported in this paper, the authors present the following discussion

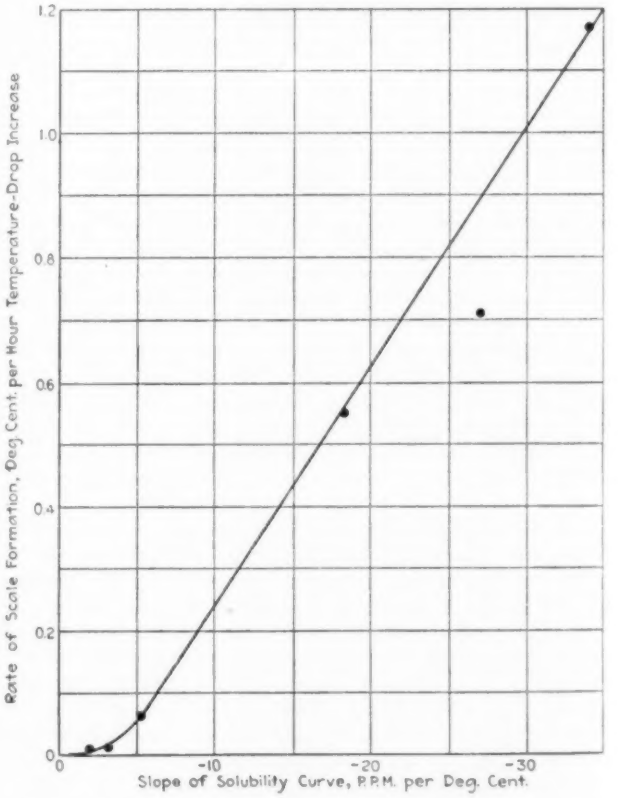

FIG. 7 RATE OF SCALE FORMATION AS A FUNCTION OF THE SLOPE OF THE SOLUBILITY CURVE

which is intended to summarize the present state of knowledge concerning the formation of calcium sulphate scale.

Calcium sulphate is deposited as scale only at heating surfaces, and does not result from the precipitation of minute crystals throughout a boiler solution with the subsequent attachment of these particles to the heating surface. The only way in which calcium sulphate may actually be precipitated in suspension is in the case of a feedwater which contains a concentration of this substance greater than the saturation value corresponding to the temperature at which the boiler is operating. For example, referring to the solubility curves of Fig. 1, if a boiler operating at 150 lb. pressure—that is, at 185 deg. cent. or 365 deg. fahr.—were supplied with a feedwater containing more than 100 parts per million of calcium sulphate, it is entirely accurate to say that minute crystals of anhydrite might be thrown out of solution throughout the body of the boiler solution. These crystals would, however, play no part in the formation of scale, other than by some accidental inclusion in the scale which would be simul-

taneously forming at the heating surfaces as the result of a quite different mechanism.

The actual scale growth depends upon two simple fundamental actions. The first of these is the formation of crystal nuclei on the hot surface by the evolution of bubbles. The actual amount of material deposited in this way by each bubble is infinitesimal, but these minute crystals are of immense importance because they serve as the initial foundation upon which the scale is built.

Since the boiler solution is saturated with calcium sulphate, these crystals on the hot surface are in contact with a fluid film slightly supersaturated, due to the increase in temperature in the film. The crystals thus cannot redissolve, but, on the contrary, tend to grow from contact with this supersaturated film. This process continues uninterrupted as long as the main body of the solution remains saturated with calcium sulphate and heat is transmitted from the hot surface to the solution. While it is probable that small amounts of material continue to be deposited by bubble evolution, nearly all of the growth of the scale subsequent to the initial deposition of nuclei may probably be attributed to the process of crystal growth from the supersaturated fluid film.

Exactly the same dual mechanism of scale formation may result in the growth of calcium hydroxide scales from feedwaters high in bicarbonate and low in sulphate or from waters overtreated with lime, since calcium hydroxide belongs to the class of substances whose solubility decreases with increase in temperature. It is probable that calcium silicate and magnesium silicate scales are also formed in this manner,[12] although solubility data for these substances at boiler temperatures are lacking.

In boilers treated internally with soda ash or with sodium phosphate the formation of thin scales which do not increase in thickness over long periods of time is reported. Since calcium carbonate is known to increase in solubility with temperature increase, the fluid film of solution at a hot surface in this case would be undersaturated rather than supersaturated, and hence any calcium carbonate crystals deposited on the surface would tend to redissolve rather than to grow. It is probable that calcium phosphate is similar to calcium carbonate in this respect. The thin scales reported may quite possibly be the result of the deposition of material by bubble evolution at a very slow rate which is almost balanced by the re-solution of the deposited crystals in the unsaturated fluid film.

Ideas advanced from time to time concerning the use of colloids and of electricity in the prevention of scale must be revised in the light of the present knowledge of calcium sulphate scale formation. Both colloidal and electrical systems for the prevention of scale have been based on the theory that scale-forming materials were precipitated throughout the boiler solution as finely divided, probably colloidal particles bearing electrical charges. The addition of protective colloids was said to cause these particles to settle out as sludge instead of forming hard scale, while electrical treatment was reputed to prevent these charged particles from approaching or adhering to the oppositely charged heating surfaces of the boiler. But it is evident from the work described in this paper that the growth of scale depends upon an entirely different mechanism than the one postulated in support of these scale-prevention systems, and any actual results from the use of colloids or electrical treatment must be ascribed to a different type of action.

The authors have made some laboratory tests which are incomplete at the present time, but which indicate definitely that many of the electrical systems proposed for the prevention of scale have no effect in stopping or decreasing the deposition of calcium sulphate scale from solutions boiling under atmospheric pressure. The use of several types of colloidal materials has also been investigated, with results that indicate that certain of these materials are adsorbed on the calcium sulphate crystals *after initial deposition* and strongly modify the physical characteristics of the scale, in some cases to such an extent that the scale flakes off from the hot surface under the influence of ordinary convection currents. It is therefore probable that some colloids may have beneficial effects in minimizing scale, although the theory advanced in support of their use has been shown to be inaccurate.

The authors have modified the solubility curves for hemihydrate and anhydrite slightly as the result of their determinations, and have advanced the theory that the rate of scale formation is proportional to the negative of the slope of the solubility curve of the scaling substance at the temperature of operation. It is probable that the rate of scale formation is also directly proportional to the rate of heat transfer across the scaling surface, although this relation has not been tested. A third factor which probably exerts an influence upon the rate of scale formation is the velocity of the boiler solution through the tubes.

Current suggestions to the effect that scale will not form upon evaporative surfaces made from specific materials are negated by the fact that the authors have produced exactly similar scales under similar conditions upon surfaces of polished steel, oxidized steel, chromium and nickel and silver plate, and glass. It was also incidentally discovered that in no case did calcium sulphate by itself produce a scale which appeared to be bonded to any degree to the surface upon which it had formed. The scales invariably cracked off cleanly from the surface. What has been referred to as the "adherence" of calcium sulphate scale is probably more accurately a bonding effect resulting from corrosion of the metal surface, combined with the considerable mechanical strength of the scale, which makes its removal from the insides of tubes far from perfectly smooth, a rather difficult piece of work.

Data available in the literature indicate that the effect of scale upon heat utilization in modern boilers is very slight. The prevention of scale in modern boiler practice is, however, becoming increasingly important from the standpoint of the elimination of tube failures due to overheating. Rather small amounts of scale formed on areas exposed to severe radiation will cause overheating of the metal and subsequent failure.

Discussion

HENRY D. FISHER.[23] A recent experience in our plant is very satisfactorily explained by the facts developed in this paper. The New Haven Pulp and Board Company recently installed a 760-hp. Bigelow-Hornsby boiler to operate at 400 lb. pressure, equipped with integral economizer, plate-type air heater, water-cooled bridgewall, and front wall and arch. The total tube area in boiler and economizer is 9234 sq. ft. and heating surface in the air heater 600 sq. ft. It is fired with a Westinghouse underfeed stoker with clinker grinder, total area 207 sq. ft., and has a furnace volume of 4800 cu. ft. single boiler up to 84,000 lb. of steam per hour.

The boiler was put under load March 18, 1929, and operated at ratings of 60,000 to 65,000 lb. of steam per hour, the load being very steady 120 hours per week, with a negligible load over week ends, until April 19, when the average was raised to 70,000 lb. per hour, with a two-hour period somewhat in excess of this. The week-end inspection showed that the fifth and ninth tubes from the left side of the bridgewall were blistered, though no rupture or leakage occurred, and the boiler was taken out of service and these tubes were replaced, as shown in Fig. 8. All the tubes were turbined, but comparatively little scale was found except in the bridgewall tubes. In these in the bare portion the scale was 0.034 to 0.049 in. thick on the side of the

[23] Plant Engineer, New Haven Pulp and Board Co., New Haven, Conn. Mem. A.S.M.E.

tube toward the fire, the thicker scale occurring toward the upper end of the tube, but becoming thinner at the sides, and on the back, against the brick wall, there was a space of $1^1/_2$ in.

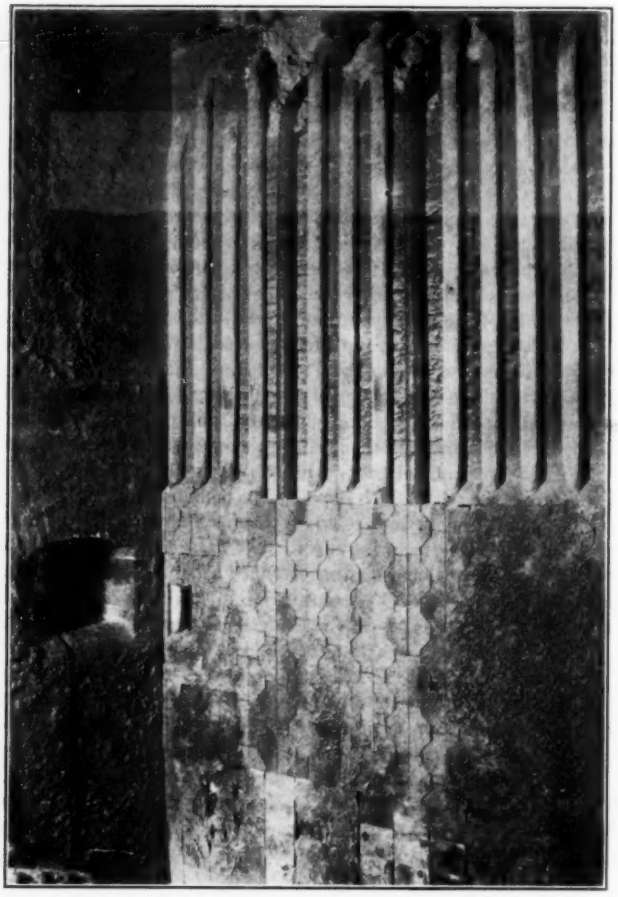

FIG. 8 SHOWING BRIDGEWALL TUBES THAT WERE BLISTERED AND REPLACED

on the circumference which showed none at all. In the covered section of the tube in the Nygaard blocks (carborundum) just below the bare section, the scale was too soft to separate in coherent chips for measurement, but did not appear to amount to more than 0.010 in. on the fire side and 0.002 or 0.003 in. against the wall, there being, however, apparently more deposit on the back of the tube than in the bare portion. Below the Nygaard blocks the tubes were covered in the square cast-iron plates machined to fit the curve of the tube and bolted up with clips. In this section the scale was a little thicker and more coherent, chips from the fireside measuring 0.012 to 0.015 in. and tapering down to a mere painting of probably 0.002 or 0.003 in. at the back.

The normal ash level in the clinker-grinder pit is about the bottom of the third cast-iron block, and it is rather surprising that the faces of some of them fused as badly as they did considering the small amount of scale in that part of the tube. Some of the blocks on the blistered tubes were also in bad shape and were replaced along with the tubes.

The source of contamination was traced to leaky process-water heaters, allowing well water to mix with the condensate. This contains considerable sulphate of lime and some magnesium salts as well as lime carbonate, and it seems quite likely that the disproportionate deposition on the front of the bridgewall tubes arose from the rapid concentration of the water in these, particularly that in contact with the front part of the tube at the high rate of evaporation occurring in them. That this was very high is evidenced by both superheat and flue-gas temperatures being almost 100 deg. fahr. below the guarantees at this rating, resulting, too, in the flue-gas temperature leaving the air heater being only about 300 deg. fahr. and the preheated air temperature in the windbox 200 to 210 deg. fahr. All this would seem to indicate a very large proportionate heat absorption in the furnace.

It is proposed to cover the remainder of the bridgewall tubes, as a careful internal inspection each week end while the boiler was in operation had shown no indication in any visible portion of the boiler tubes of the existence of such a dangerously scaled condition, and manufacturing conditions are too little under the control of the operating force to ensure against a repetition of such contamination, although evaporators were provided for supplying distilled make-up and the chances of contamination were believed much more remote than the event showed.

AUTHORS' CLOSURE

E. P. PARTRIDGE. The experience cited by Mr. Fisher offers a practical demonstration of the effect which a small amount of scale may have upon a boiler surface exposed to extreme heat radiation. The distribution of scale is particularly interesting, since the thickness of the deposit in different regions seems to have been proportional to the probable rate of steam evolution in these regions. I would be very glad to obtain information, samples of scale, or small sections of scaled tube from any one having a similar experience.

FSP-51-50

Present Status of Tests for Refractories

By STUART M. PHELPS[1] and J. SPOTTS McDOWELL,[2] PITTSBURGH, PA.

Tests for refractories may be divided into three general types: durability, suitability, and control. Durability tests can be made only in industrial furnaces, under actual operating conditions. Suitability tests may be carried out in the laboratory, under conditions which simulate those of service as closely as possible. Control tests, for maintenance of uniformity of product, should be relatively simple and require only a short length of time to perform. The pyrometric cone equivalent gives an index of refractoriness, but is not a measure of the actual temperature which a material will withstand under long-continued heating. The standard load test is not an index of refractoriness, but is a good control test, especially for brick to be used under load at high temperatures. Difficulties of interpretation affect the value of reheat and spalling tests. The most useful specifications are those of the control type.

MODERN developments in furnace design and operation have been such as to impose increasingly severe service upon the refractory linings. Operating and maintenance costs are in no small measure dependent upon the selection and use of lining materials which are adapted to the service conditions. Continuity of operation, together with the frequency and extent of repairs, is determined by the degree to which the refractory material is adapted to its environment. Among the most important environmental conditions are intensity of the heat, temperature fluctuations, action of slags and reducing gases, static loads, and furnace design. These conditions impose upon the refractories the requirements of resistance to fusion, spalling, slag erosion, and distortion. As there are wide variations in furnace practice, there must be corresponding variations in the properties of the lining materials if best results are to be secured.

General Types of Tests

The study of the properties of refractory materials and of suitable methods of testing them has long engaged the attention of investigators. Chemical analysis and resistance to fusion were the first subjects investigated; later came studies of distortion under load, slag erosion, spalling, and constancy of volume at high temperatures. In much of this early work it was regarded as of fundamental importance that the tests be relatively simple, inexpensive, easily duplicated, and require only a short length of time to perform. The general adoption of tests of this character has greatly facilitated the study of refractories. Specifications based upon them have made possible a study of the possibility of correlating laboratory results with those of service. The data accumulated during a period of several years have demonstrated that while in some cases the correlation is fairly satisfactory, laboratory results frequently offer no criterion as to the probable life of a refractory material. This is not surprising, since the conditions under which the tests are made are usually not comparable with those of service. It is now becoming generally realized that more than one type of testing is required, depending upon the purpose for which the data are required. The three general types may be classified as follows:

1 Durability tests
2 Suitability tests
3 Control tests.

Durability tests can be made only under actual service conditions. To be of greatest value, ample data must be obtained both as to the properties of the refractory material under investigation and the conditions in the furnace during the test period. Results obtained upon merely a few brick are usually of little if any value. In order to obtain conclusive results, it is essential that an entire section of the furnace be constructed of the material under test.

Suitability tests should simulate service conditions as closely as possible within the limitations of laboratory procedure. The usual short-time tests can rarely be regarded as measures of the suitability of a refractory material in service, as they do not give sufficient consideration to the time factor and to other important variables. The development of suitable simulative service tests is now receiving the attention of various groups of investigators, and much progress along this line during the next few years may be anticipated. The A.S.M.E. Special Research Committee on Boiler-Furnace Refractories has made contributions of much value in this connection. The work on slag erosion being conducted for the committee by the University of Illinois is of special importance. The Refractories Fellowship of the Mellon Institute is conducting extensive research upon service spalling tests.

Control tests are indispensable to the manufacturer of refractories and extremely useful to the consumer. Their primary function is maintenance of uniformity of product based upon certain standards arbitrarily established as a result of experience. Control work logically begins with the raw material and follows through the various stages of manufacture to the finished product. For plant control or control of shipments it is desirable that the tests be such as can be quickly conducted with relatively simple apparatus. On unburned material, the tests commonly applied are chemical analysis, refractoriness (pyrometric cone equivalent), moisture content, screen analysis, and porosity and shrinkage under definite heat treatment; on finished brick, chemical analysis, refractoriness, porosity, density, mechanical strength, rigidity, and constancy of volume at elevated temperatures as well as resistance to rapid thermal changes.

A brief discussion will here be given of some of the more important tests.

Pyrometric Cone Equivalent

The P.C.E. test is one of the oldest and most widely used of all the present tests. It is conducted by heating in a suitable furnace a small portion of the sample, ground and molded into the form of a small tetrahedron or "cone," together with a series of standardized cones of definite compositions. These fuse at definite temperatures, the intervals between cones being about 20 deg. cent. They must, however, be heated at a definite rate to cause fusion at known temperatures; if heated more slowly, they fuse at much lower temperatures. It is essential that all P.C.E. tests be conducted with the same rate of heating over a total period of only a few hours. It is obvious that the index of refractoriness supplied by the P.C.E. is not necessarily applicable to conditions where the time of heating may be weeks or months.

The results should always be given in standard cone numbers

[1] Senior Fellow, Refractories Fellowship, Mellon Institute of Industrial Research.

[2] Director of Research, Harbison-Walker Refractories Company.

Contributed by the A.S.M.E. Special Research Committee on Boiler-Furnace Refractories and presented at the Rochester Meeting, Rochester, N. Y., May 13 to 16, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

and not in temperatures, as the temperatures are accurate only for the standard rate of heating and the results cannot be used to predict the actual temperature which a material will withstand under long-continued heating.

P.C.E. determinations are conducted in a short time and give fairly consistent results. For a given laboratory the results should check within plus or minus one cone, and for most materials within less than half a cone. The test is of great value in connection with the control of raw materials. Maintenance of uniformity of quality is facilitated by the preparation of charts of the type shown in Fig. 1. Although valuable in the control of finished products, the pyrometric cone equivalent cannot be safely used as an index to their refractoriness without supplementary data. This may be shown by considering a brick made of fused alumina bonded with a low-grade clay. The P.C.E. of this mixture would be high, but its heat-resisting qualities in service would be low. This example is extreme, but the principle often applies. Examples are given in Table 1, which gives refractoriness values for a number of "super" refractories.

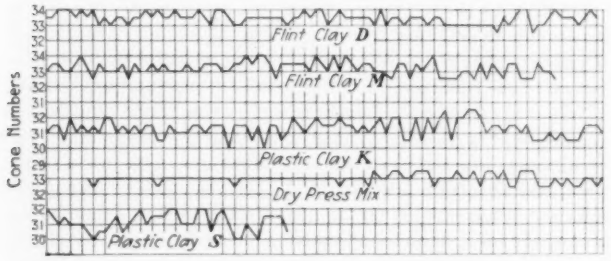

FIG. 1 P.C.E. DATA ON WEEKLY SAMPLES

TABLE 1

Sample	P.C.E.	Subsidence in load test at 1500° C. under 50 lb. per sq. in., per cent	Bending of brick under load with a span of 7 in., temperature 1600° C. mm.
1	37	0.2	1.0
2	37	2.2	1.6
3	36–37	0.4	2.8
4	Above 38	5.8	Broke

Sample 4 shows the highest P.C.E. value, but is poorest in both the load and bending tests.

STANDARD LOAD TEST

The test is conducted by heating the brick at a definite rate, with a load of 25 lb. per sq. in. applied on end, to 1350 deg. cent., which is maintained 1½ hours. The data are of considerable value when properly used, although the interpretation now given the results differs considerably from that of some years ago. The test was originally regarded as a determination of "quality;" it is now known that the results are affected not merely by the character of the raw material from which the brick were made, but also by the fineness of texture, the process of manufacture, and the temperature of firing. For a given brand of fireclay brick the deformation may vary from 2 to 10 per cent, depending upon the degree of burn.

Recent tests conducted in a special load-test furnace[3] in which ten brick may be tested at one time under identical conditions show that the variation between samples is relatively large. The data presented in Table 2 are of interest, since the ten brick tested from each lot are as uniform as may be expected from commercial products. It is obvious from this that a figure determined by testing only one specimen is of little value as an indication of the true characteristics of a brand.

[3] Technologic Paper No. 2, American Refractories Institute.

TABLE 2 PERCENTAGE OF SUBSIDENCE IN LOAD TESTS CONDUCTED AT 1350 DEG. CENT. UNDER A PRESSURE OF 25 LB. PER SQ. IN.

Sample	Brand A, Cone 32–33 Brick Result	Brand A, Cone 32–33 Brick Deviation	Brand B, Cone 30 Brick Result	Brand B, Cone 30 Brick Deviation
1	3.8	+0.7	8.2	−0.4
2	3.7	+0.6	8.8	+0.2
3	3.4	+0.3	9.7	+1.1

9	2.3	−0.8	7.8	−0.8
10			6.8	−1.8
Mean	3.1	...	8.6	...
Standard deviation	...	0.5	...	1.7

Fig. 2 presents a view after testing of the brick shown as "Brand B" in Table 2. The bricks at each end of the row were not included in the test; by comparison the variation in the subsidence of the brick which were tested can be noted. The cone plaques in front of each brick were upon the respective brick during the test and show the uniformity of the furnace temperature.

Load-test conditions, in which the brick are heated throughout, are not comparable with conditions in the wall of a boiler setting, in which only one end of the brick is exposed to the heat, resulting in a temperature gradient between the inner and outer faces. The lack of concordance to be expected between test data and behavior in service is illustrated by an experiment conducted at the Mellon Institute. Brick of a brand which showed unusually high deformation in the standard load test were laid up in a small furnace in the form of a panel 9 in. thick, with the outside surface thoroughly insulated to simulate the most severe conditions

FIG. 2 BRAND "B" AFTER LOAD TEST

of service. A pressure of 25 lb. per sq. in. was applied to the wall, the furnace temperature being 1350 deg. cent. The brick showed no measurable deformation under these conditions, although under standard load-test conditions, at the same temperature and pressure, other brick of the same lot deformed 22 per cent.

The load test, like many others, has its greatest usefulness in control work. It is frequently useful as a means of classifying various brands of brick into groups, for service in which rigidity at high temperatures is an essential requirement.

THE REHEAT TEST

The object of the reheat test is to determine the constancy of volume of brick at a temperature higher than that at which they were burned. In the standard method they are heated in 4½ hours to 1400 deg. cent., and maintained at that temperature for 5 hours. From measurements taken before and after testing, the percentage of linear change is calculated.

Recent studies have shown that many brick of high refractory value exhibit in the reheat test expansion phenomena similar to those of overfiring. The cause of this so-called "secondary expansion" is obscure. It renders difficult the interpretation of reheat test data, for one cannot always be sure whether an abnormally high expansion results from overfiring, and is therefore an indication of inferior quality, or whether it is merely a

"secondary expansion" which has no significance in service. However, a brick which shrinks in the test will probably do so in service.

The data presented in Table 3 show that there is no appreciable difference in the linear change of high-grade brick heated to 1400 deg. cent. in 4½ hours or in 60 hours. Comparison of these changes with those produced by 98 days' continuous heating in a commercial tunnel kiln shows that there is no relation between the figures in the standard reheat test and change of volume in service.

TABLE 3 PERCENTAGE OF LINEAR CHANGE OF FIRECLAY BRICK IN REHEAT TESTS

Brand	Regular reheat test, 4½ hr. to reach 1400° C., 5 hr. at 1400° C.	Special reheat test, 60 hr. to reach 1400° C., 5 hr. at 1400° C.	98 days of continuous heating in tunnel kilns Cone 13 kiln (1300° C.)	Cone 17 kiln	Periodic kiln Cone 12	Periodic kiln Cone 15
1	+0.3	+0.4	+3.1	+ 5.3	...	...
2	+0.4	+0.6	−4.7	− 6.9	...	...
3	+0.8	+0.9	−1.4	+ 1.8	...	...
4	+1.0	+1.1	−0.6	− 2.1	...	...
5	−0.4	−0.2	−0.2	−11.8	...	...
6	−1.2	−1.2	−3.0	− 5.9	...	...
7, green brick	+1.3	+1.1	...	...	−1.0	...
7A, soft burned	+1.3	+1.1	...	...	...	0.0
8, green brick	+1.6	+1.3	...	...	−1.0	...
8A, soft burned	+1.1	+0.6	...	...	...	−0.8

Additional studies are planned to learn the effect of furnace atmosphere upon the results. Furnace atmosphere has not been given the consideration which its importance merits in test procedures.

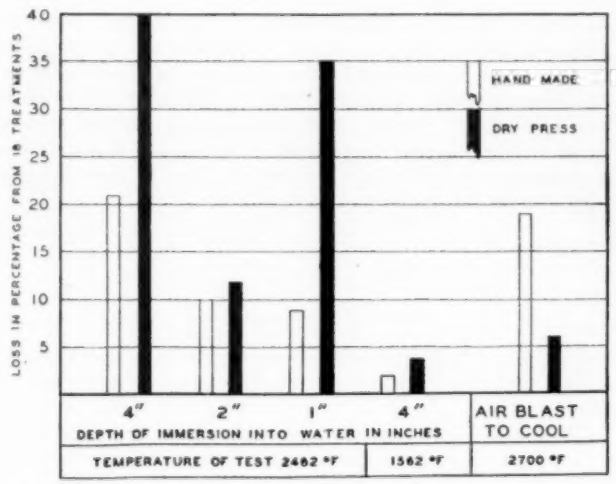

FIG. 3 BEHAVIOR OF TYPICAL HAND-MADE AND DRY-PRESSED BRICK IN FIVE TYPES OF SPALLING TESTS

WATER-IMMERSION SPALLING TEST

The water-spalling test has been the subject of much controversy. It originated at a time when the only type of spalling considered was that which results from rapid temperature changes or thermal shock. It is now realized that this cause of spalling is often of minor importance, and therefore that any test which gives only an index of thermal spalling is inadequate.

The water-dip test in itself is not satisfactory for the thermal-spalling phase. It is too severe in its method of cooling the heated ends of the brick and is subject to large errors. The character of vitrification produced in service at the hot ends of the brick is not simulated. The most severe thermal changes encountered in service will rarely spall clay brick unless they become vitrified to a measure through the action of heat, slags, or fluxes in the gases.

Fig. 3 gives a comparison of two brands of fireclay brick, one hand-made and the other dry-pressed, tested in five different ways. It will be observed that, according to two methods of testing, the hand-made brick appear to be superior to the dry-pressed; in two, about equal; and in one, inferior. Obviously such contradictory results cast doubt upon all the methods indicated. The service spalling test, now in process of development at the Mellon Institute, offers great promise of a close correlation of laboratory data and life in service. A section of a furnace wall is simulated by applying the necessary insulation and pressure upon ten brick laid up in a panel in the manner illustrated in Fig. 4. The surface of the panel is first heated so as to produce vitrification comparable with that of furnace walls; subsequently, it is cooled by means of an air blast.

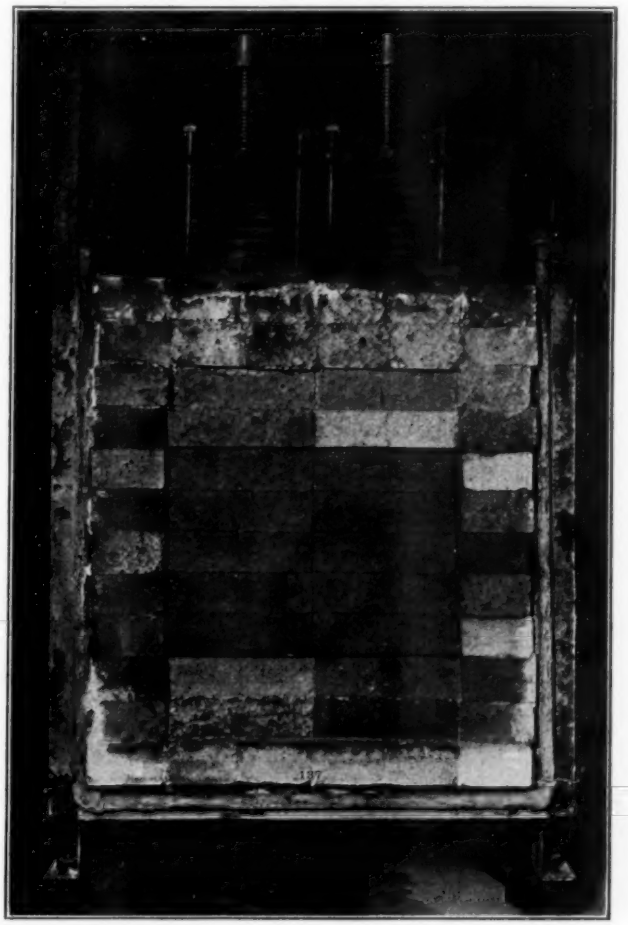

FIG. 4 TEST BRICK ARRANGED IN PANEL FOR SERVICE SPALLING

USE OF TESTS IN SELECTION OF REFRACTORIES

Analysis of the service conditions in a given furnace will reveal the requirements which the brick should meet. Requirements differ in different furnaces, and often in different parts of the same furnace. In many cases all of the properties desired cannot be incorporated in one refractory material. For example, there is no refractory material that is resistant to oxidation and that has also the exceptional rigidity of silica brick at high temperatures and the high resistance to spalling of many fireclay brick.

In the case of fireclay brick, due regard must be given to the

fact that certain properties have a relationship which cannot be changed except within narrow limits. An example of this is afforded by the effect of the degree of firing upon fireclay brick, as shown graphically in Fig. 5. The relations shown are not fixed and invariable, but are merely general tendencies. They are further illustrated by brands 1 and 2 of Table 4. The pronounced increase in cold strength, rigidity at high temperatures, and constancy of volume in the reheat test, resulting from hard burning, is apparent. The elasticity and resistance to thermal shock, however, have been decreased. This detrimental effect of hard burning upon thermal spalling often prevents the use of hard-burned brick in service where they would otherwise be desirable.

TABLE 4 TESTS OF FIRECLAY BRICK

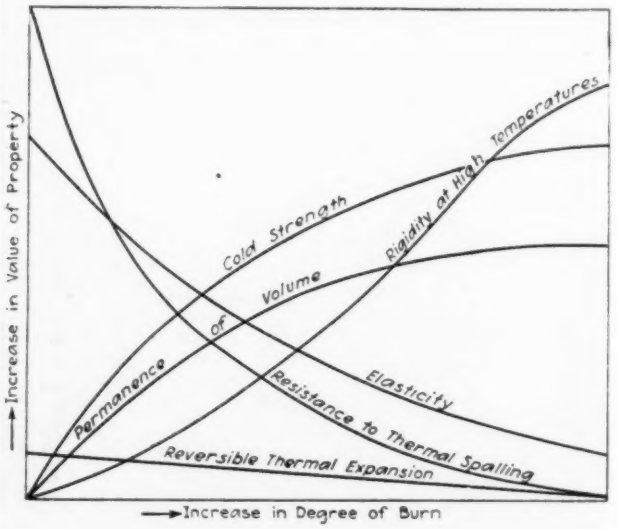

FIG. 5 CHART SHOWING EFFECT PRODUCED BY VARYING THE DEGREE OF BURN OF CLAY BRICK

The brands of brick listed in Table 4 are known to give good service in boiler furnaces. The data given show that, while all have the same P.C.E. value, their behavior in other tests is very different. This condition illustrates the difficulty of so drafting specifications as to include the various brands which will give good service and at the same time to have the requirements specific.

Various specifications used for the selection of refractories have served the highly useful function of demonstrating wherein laboratory methods are imperfect or the results improperly interpreted. They have stimulated investigations which are leading to the development of more suitable test procedures.

The most useful specifications are those of the control type. Service tests are required for conclusive evidence as to the best type of refractory for a given practice. Once this is definitely known, a specification with reasonable limits and tolerances may be drafted based upon the properties of the material known to give satisfactory service. Proper consideration must be given to the degree of precision of the laboratory methods. Limits and tolerances which are too extreme in either direction will not lead to adequate control. Such specifications, written with a broad understanding of the methods of testing and of the service requirements, will stimulate research and lead to more definite correlation of laboratory and service data.

FSP-51-51

Study of Some Factors in Removal of Ash as Molten Slag From Powdered-Coal Furnaces[1]

By RALPH A. SHERMAN,[2] P. NICHOLLS,[3] and EDMUND TAYLOR,[4] PITTSBURGH, PA.

The purpose of this investigation, which was conducted at the Toronto, Ohio, station of the Pennsylvania-Ohio Power and Light Co., in cooperation with Stevens & Wood, Inc., New York, was to study those factors governing the application of the slagging method of ash removal which are related to the characteristics of the ash of the coal burned. The history of the development of and the merits of slagging furnaces are briefly discussed, and the results of observations made when burning three coals, whose ash had fluid temperatures of 2400, 2600, 2800 deg. fahr., in a furnace fired with horizontal burners and having bare water tubes set on three walls, are presented. The following studies were made: (1) The condition of the slag in the hearth and on tapping; (2) the temperature of the slag; (3) the temperature and composition of the gases near the slag bed; (4) the relation of the composition and fusion temperatures of the slag and the dust carried out of the furnace to those of the original ash; (5) the percentage of the ash fired which was carried out of the furnace and stack; (6) the relative temperatures of the gas entering the boiler tubes in two furnaces, one with a lower water-tube slag screen and the other with a slagging bottom; and (7) a brief study of the amount of flux necessary to add to a given ash to obtain a fluid slag.

THIS paper presents the results of an investigation of the removal of ash as molten slag from furnaces burning powdered coal at the Toronto, Ohio, station of the Pennsylvania-Ohio Power and Light Company, in cooperation with Stevens & Wood, Inc., New York City. The purpose of the investigation was to study those factors governing the application of the slagging method of ash removal which are related to the characteristics of the ash of the coal burned.

SLAGGING FURNACES

Development

The removal of ash always presents difficulties in the burning of coal, whether on stokers or in powdered form. In the early trials of powdered coal the tendency of the ash to melt in the flame and then solidify in the lower part of the furnace was one of the most serious problems encountered and led to the development of water-tube slag screens, water-cooled ashpits, and water-cooled furnaces which are intended to absorb heat from the ash and thus prevent its deposition in the molten state. Even with these devices, however, it is rare with some coal and with some conditions of operation that difficulty is not encountered with accumulation of solidified slag in the ashpit and consequent difficulty in its removal. Fig. 1 shows an extreme case of this accumulation which necessitated the removal of the boiler from service once a month in order to mine out the slag.

Because of this common tendency of the ash to become fluid it was natural that attempts should be made to remove it in the molten state. Anderson[5] has stated that the removal of ash as molten slag was of necessity the original method used at the Oneida Street station in Milwaukee, Wis., before screen tubes were added. Blizard[6] reported that in 1919 an installation in Seattle was designed for this process, but inquiry has shown that it has never been followed as a practical measure. Experience with this method of ash removal in France was reported at the Second Congress on Industrial Heating in 1928. Weiss and Munier[7] reported their experiences which date back to 1920 and state:

> We were forced to conclude that the utilization of powdered coal with molten ash was not of general application because it was successful only with certain classes of coals having easily fusible ash and was not suited to the class of coals which we were using.

FIG. 1 EXTREME EXAMPLE OF SLAG ACCUMULATION BELOW WATER-TUBE SLAG SCREEN OF POWDERED-COAL BOILER

Schereschewsky[8] reports that the discussion which arose in earlier years in France between the partizans of molten ash and pulverulent ash seems to have disappeared, and now only 22 boilers totaling about 52,000 sq. ft. of heating surface, or about 5 per cent of the total powdered-coal installations, are operating with removal of molten ash.

The early experience with slagging furnaces was therefore not particularly favorable, so that the trials at the Charles R. Huntley[9] Station of the Buffalo General Electric Company and at the Toronto, Ohio, station, while not an innovation, were at least new in their successful application in the United States.

Merits

The Fuller-Lehigh Company recently stated[10] that they have equipped 11 boiler units with slagging furnaces and have 15 units under construction; and further, that

....experiences with some furnaces during the past two years and with other furnaces that are now going into operation indicate

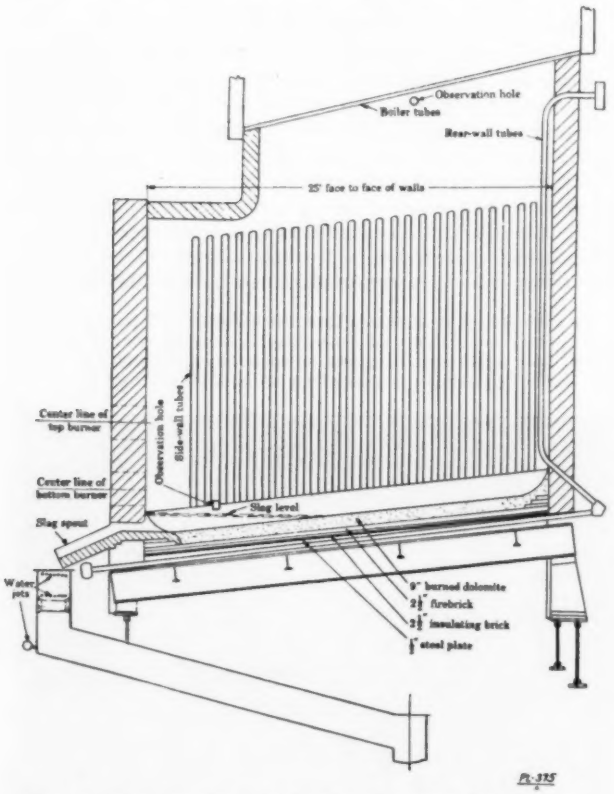

Fig. 2 Side-Sectional Elevation of Boiler No. 4 With Slagging Bottom, Toronto Station

that this is an ideal method of handling ash from pulverized-coal furnaces....With horizontal turbulent burners in the lower part of the furnace, there is no difficulty in handling ash having a fusing temperature as high as 2500 or 2600 deg. in a satisfactory molten condition. With very high temperatures in the floor and walls immediately surrounding the ash, turbulence can be had in this space with the flames impinging directly upon the floor without any fear of damage. Other advantages of this furnace are reduction in height of building and the use of a simple ash-removal system. The ash is removed in a very satisfactory manner by means of a water jet with a minimum of labor, and the boiler room is kept clean and free from dust.

INVESTIGATION OF SLAGGING METHOD

Origin of Investigation

The trials of the slagging method at the Toronto station were occasioned by the usual difficulty of the accumulation, under certain conditions of operation, of masses of solid slag in the ash-pits which could not be removed by the regular sluicing system. A slag hearth was installed first in the furnace of boiler No. 5, which was equipped with Bailey refractory-faced water walls and was fired with Bailey Calumet vertical inter-tube burners. A second installation was made in the furnace of boiler No. 4, which had refractory walls protected on the side and rear by bare water tubes and was fired with horizontal Peabody Toronto burners. The ash has been removed from these two furnaces by tapping off the molten slag approximately once every 24 hours under all normal conditions of boiler operation since April, 1928.

As the designing and constructing engineers of the Toronto Station, Stevens & Wood, Inc., desired information on the relation of the characteristics of the coal ash for various coals to those of the slag formed, they requested the Bureau of Mines to cooperate with them in an investigation.

Analysis of Problem and Scope of Investigation

The two available measures of the properties of coal ash are the "cone" test and chemical analysis, between which no definite relation has been established. The fluid temperature determined by the cone test is probably some indication of the temperature which must be attained in the hearth of a boiler furnace in order that the ash may be removed as molten slag. However, the temperature of the slag must be higher than that at which it will just flow, so that the loss of heat at the walls, at the tap hole, and in the spout will not cause freezing.

The average maximum temperature attained in boiler furnaces does not often exceed 2800 deg. fahr.,[11] and the temperature of the hearth will naturally be lower, probably by at least 100 deg. It would be expected, therefore, that the upper limit of fluid

Fig. 3 Interior of Furnace of Boiler No. 4, Toronto Station
(Showing powdered-coal burners and top of slag bed.)

temperature of an ash which would flow satisfactorily would be 2500 to 2600 deg. if that deposited on the hearth had the same composition and fluid temperature as the ash fired to the furnace.

Data have been presented, however, which indicate that the

[10] *Power Plant Engineering*, vol. 33, p. 104, 1929.

[11] Fahrenheit scale used throughout this paper.

ash which is deposited at the bottom of the furnace may differ in composition and fluid temperature from that in the original coal. Sherman and Taylor[12] have reported that the softening temperature was lower and the content of iron and lime was higher in the material which collected on the water screens and on the walls than in the original coal ash in two furnaces burning powdered Illinois coal with long-flame burners. Jacobus and Bailey[13] reported that they had found the softening temperature of the material remaining in the furnace lower, and that of the dust leaving the furnace higher, than that of the original ash. They reported a large number of samples from various installations but did not give their composition.

The principal requirement in this investigation was therefore to determine the relation in the Toronto slagging furnaces between the composition and characteristics of the coal ash, the slag from the hearth, and the dust carried out of the furnace. In addition data were obtained on the amount of dust carried out of the furnace, the temperatures in the slag bed, and on the temperature and composition of the gases above the hearth.

Data were obtained for all of these factors in the furnace of boiler No. 4 when burning three coals, the two normally burned at the station, one from a strip mine in the Ohio-Pittsburgh No. 8 bed, hereafter called strip-mine coal, the other from underground mines in the Pennsylvania Pittsburgh No. 8 bed, hereafter called Pittsburgh coal, and a special coal brought in for the tests from the Georges Creek district of the Pittsburgh Big Vein, hereafter called Georges Creek Coal. Observations were made in the furnace of boiler No. 5 only when burning Pittsburgh coal.

In boiler No. 4 the action of the slag bed was observed and data were taken over two periods of 6 days each when burning the strip-mine coal, over two periods of 5 days each when burning the Pittsburgh coal, and over one period of 4 days when burning the Georges Creek coal; in boiler No. 5 data were taken over a period of 8 days.

DESCRIPTION OF FURNACES

Boiler No. 4. Fig. 2 is a side-sectional elevation of the furnace of boiler No. 4, and Fig. 3 is a photograph of the front wall which shows the powdered-coal burners and the top of the slag bed. The boiler operated at 375 lb. gage pressure; it had 20,470 sq. ft. of heating surface, and the area of heating surface of the bare tubes set in front of the refractory of the side and rear walls and over the ashpit was 2100 sq. ft. The volume of the furnace above the slag bed was 12,750 cu. ft.

The square in the lower front corner of the furnace, Fig. 2, marks the hole through which samples were taken from the slag bed and various observations were made; the circle just below the tubes marks the hole through which dust samples were taken and temperature measurements were made.

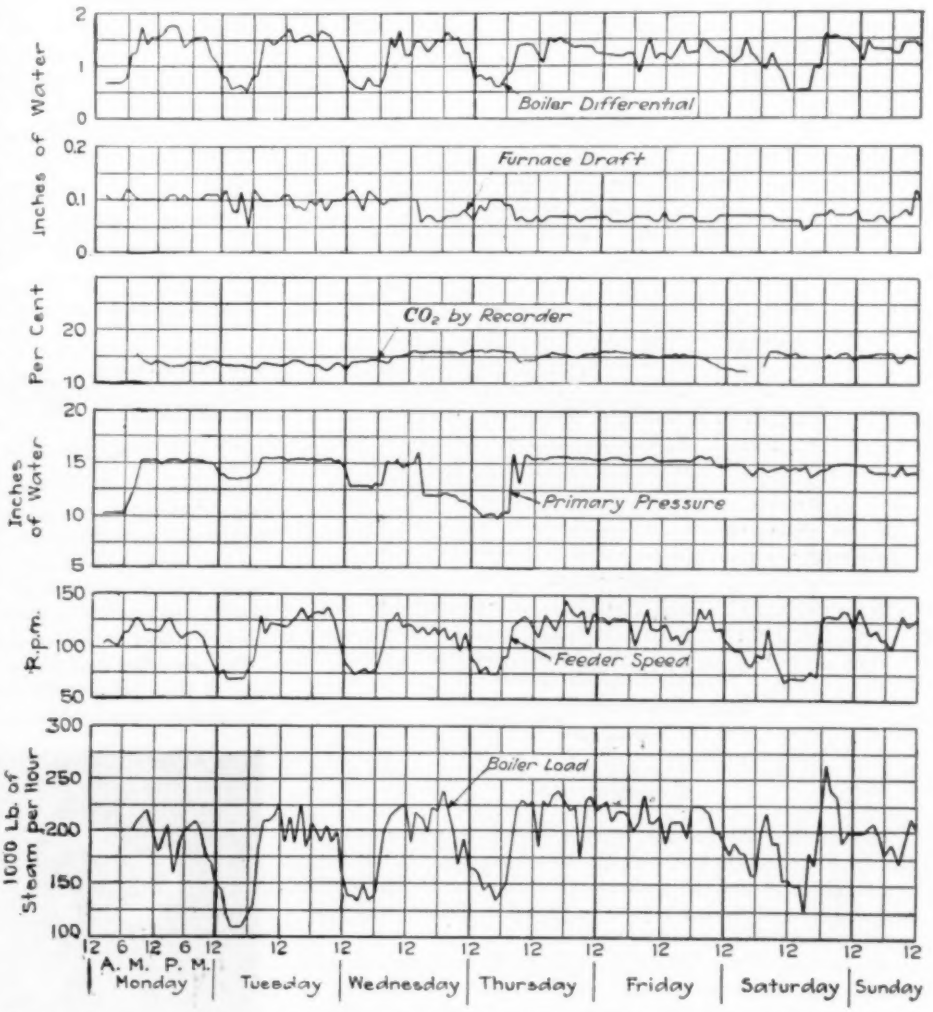

FIG. 4 TYPICAL LOG BOILER OPERATION, BOILER NO. 4, TORONTO STATION, NOV. 12 TO 18, INCL., 1928

The normal, maximum, and minimum loads on the boiler were respectively 210,000, 250,000, and 140,000 lb. of steam per hour; at these loads the rates of heat liberation were approximately 21,000, 26,000, and 13,000 B.t.u. per cu. ft. of combustion space per hour. Fig. 4 is a typical week's log of the boiler.

The hearth was made up, as indicated in Fig. 2, of a steel plate, $2^1/_2$ in. of insulation, $2^1/_2$ in. of firebrick, and 9 in. of burned dolomite placed on the sloping water-tube slag screen. The dolomite was only loosely packed on the bottom. Because of the slope of the hearth the area for slag accumulation was limited to about half the area as the height of the slag was then at the bottom of the burner openings. In order that the slag could be completely drained from the hearth it was necessary to place the

[12] Sherman, R. A., and Taylor, Edmund, "Refractories Service Conditions in Furnaces Burning Powdered Illinois Coal With Long-Flame Burners," Trans. A.S.M.E. Fuels and Steam Power Section, vol. 50, no. 15, pp. 125–140, 1928.

tap hole at the lowest point, in a front corner, which was in an unfavorable position relative to the high-temperature zone of the furnace.

Boiler No. 5. Fig. 5 is a side-sectional elevation of the furnace of boiler No. 5. This boiler operated at 400 lb. gage pressure; it had 21,620 sq. ft. of boiler heating surface, and the area of the refractory-faced blocks on the front, side, and rear walls was 2578 sq. ft.

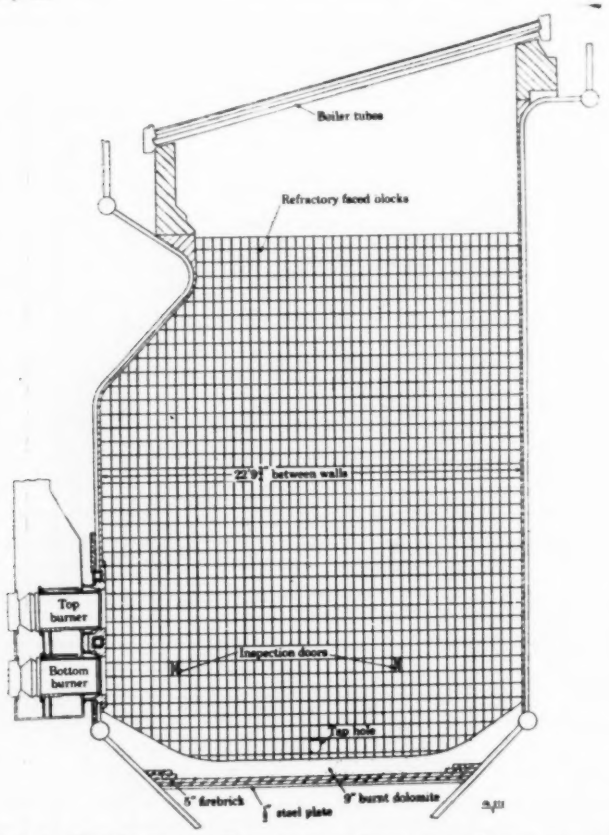

FIG. 5 SIDE-SECTIONAL ELEVATION OF FURNACE OF BOILER NO. 5, TORONTO STATION

The hearth of this furnace, which was of similar construction to that of No. 4, was installed above the ash hopper. It was horizontal, which allowed the accumulation of slag over the entire area and also allowed the tap hole to be placed in the side wall halfway between the front and rear walls.

At the time of the tests Peabody Toronto burners had been installed in this furnace. These were similar to those used in No. 4, except that provision was made for the admission of tertiary air around the burner on the furnace side.

The coal for both furnaces was pulverized in roller mills and fed to the burners from an overhead bunker by screw feeders. The coal and primary air entered tangentially to the barrel of the burner, and the secondary air entered in the center. The air and coal were mixed by their rotary motion in the barrel, which was rifled; the coal ignited near the face of the burner. The air was heated in a plate-type heater to about 300 deg. at normal load.

The tap holes were plugged with fireclay between tappings; on tapping, this was removed with a bar and sledge, and the slag flowed in the refractory-lined spout to fall into jets of water where it was granulated by the sudden cooling and was carried out by the water through the ash sluice. Fig. 6 shows the operation of tapping furnace No. 4.

CHARACTERISTICS OF COAL AND ASH

Table 1 gives the proximate and ultimate analyses, and calorific value on the dry basis, the size of the powdered coal, and the initial deformation, softening, and fluid temperatures of the ash of the three coals burned. The analyses are of composite samples made up of the indicated number of daily samples.

TABLE 1 PERCENTAGE ANALYSES OF COAL AND ASH

	Coal		
	Strip-mine	Pittsburgh	Georges Creek
No. of daily samples included.	4	4	2

Fluid temp., deg.	2360	2400	2520	2570	2640	2730	2790	2790	2800

METHOD OF INVESTIGATION

Handling of Coal. In burning the three coals care was taken to insure that only one coal was reaching the boiler. A raw-coal bunker was carefully cleaned, filled with the coal to be burned, and the level in the powdered-coal bunker was brought to the lowest possible point before the pulverizing mill was started. Thus it was possible to know within an hour when the new coal was being fired to the furnaces.

The powdered coal was sampled at half-hour intervals at the base of the cyclone collector and accumulated over 24 hours. Analyses were made of the daily samples.

FIG. 6 TAPPING MOLTEN SLAG FROM BOILER NO. 4, TORONTO STATION

Measurement of Temperature. The temperature of the furnace gases was measured by means of a platinum, platinum-rhodium thermocouple which was protected and supported in a water-cooled tube. The hot junction and $1^1/_2$ in. of the wires were directly exposed to the gases.

The temperature of the slag was measured by means of a plati-

num, platinum-rhodium thermocouple protected from contact with the slag by a closed-end fused-silica tube; it was supported in a water-cooled tube for measurements in the slag bed of the furnace and in an iron pipe for measurements in the flowing slag in the spout. All thermocouples were frequently checked by comparison with a standard thermocouple.

Sampling Gases. Samples of gases were taken from the furnace through water-cooled sampling tubes, collected over an acidified, saturated solution of salt, and analyzed in an orsat apparatus for CO_2, O_2, CO, H_2, and CH_4.

Sampling Slag. Because a large amount of slag from the coal previously burned always remained in the furnace, in the slag bed, and on the walls and tubes, the samples for analysis and comparison with the composition of the coal ash and flue dust were not taken until at least two days after a change in the coal.

Samples of the slag flowing in the spout were taken with an iron ladle, and samples from the furnace by dipping a water-cooled copper tube into the molten slag.

Sampling Dust From Gases. Fig. 7 shows the water-cooled tube used for sampling dust from the gases within the furnace below the boiler tubes and the collector and filter in which the dust was removed from the gas. The construction of the sampling tube is clearly shown; nickel is used for the inner tube because it is corroded less than copper by the sulphur acids in the gas.

The gas carrying the dust enters the tube at the left which curves toward the side of the bottle so that a large part of the dust is thrown out on the bottom of the bottle. The remainder of the dust is removed as the gases pass through the parchment thimble and the volume of gas is measured by an orifice meter. The dust which settles in the sampling tube is removed and added to that collected in the bottle.

Fig. 8 shows the apparatus used for sampling dust from the gases at the discharge of the induced-draft fan. The gas and dust are drawn through the 1-in. knife-edged pipe and enter the col-

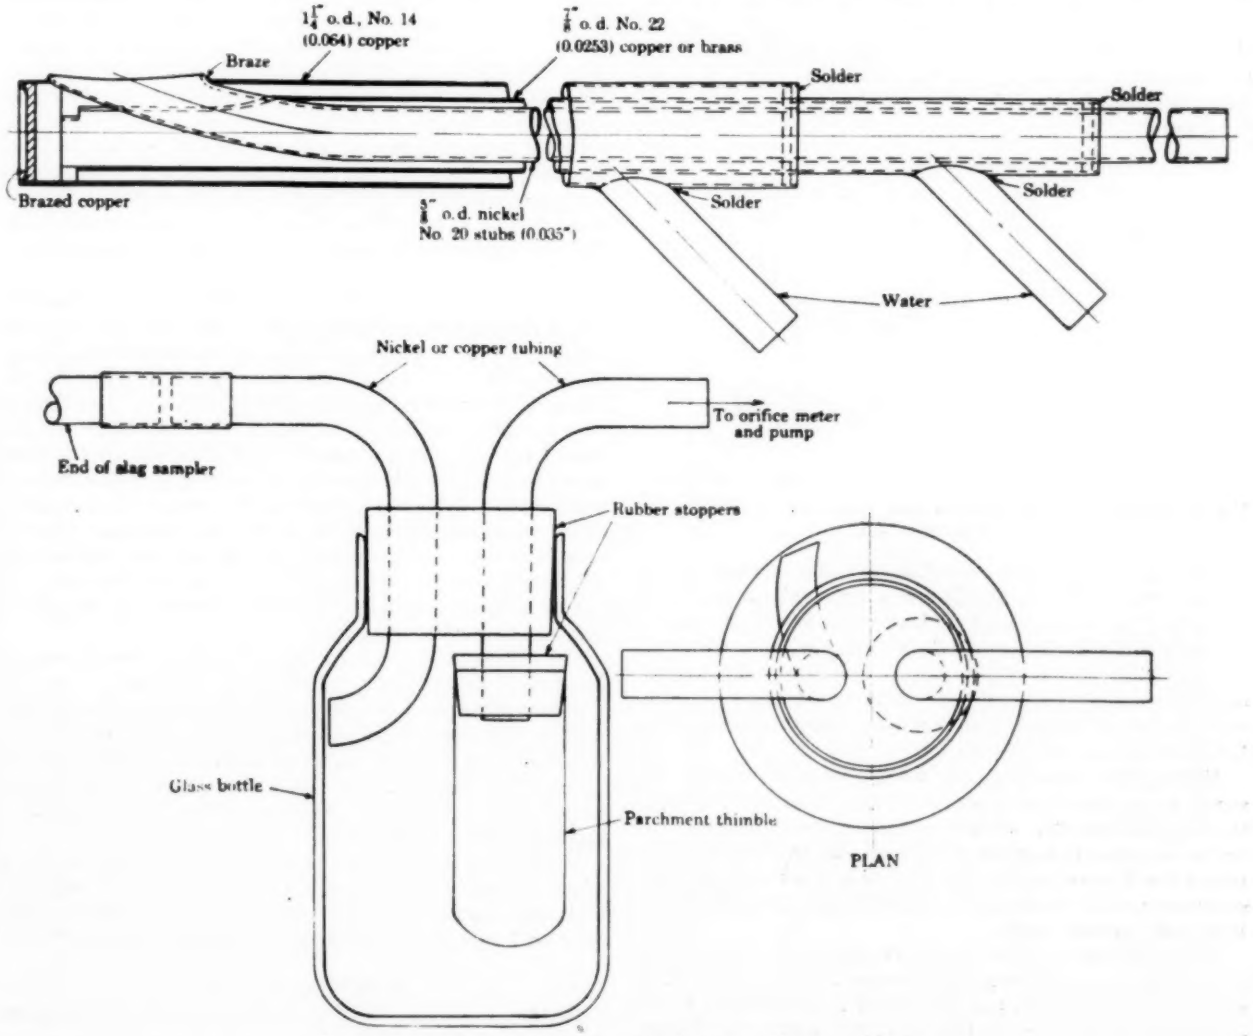

FIG. 7 SAMPLER AND COLLECTOR FOR SOLIDS IN FURNACE GASES

lecting bag made of feather-proof ticking which is supported in the welded metal container. The volume of gas is measured by an orifice meter. This method of dust sampling was developed by the test engineers of the Toronto station and the results presented in this paper were obtained by them.

With both types of samplers the open end of the sampling tube faced the direction of gas flow and the rate of flow was set so that the linear velocity of entrance to the tube was the same as that of the gas at the point of sampling. The velocity of the gases in the furnace was determined by means of a water-cooled pitot tube; the velocity in the stack was calculated from the rate of firing,

the flue-gas analysis, and the area of the flue; it was checked by a pitot tube at one load and the calculated value was found to be correct.

The efficiency of the ticking bag as a filter for dust was determined by drawing a part of the gas through the parchment thimble collector after it had passed through the bag. The weight of dust caught by the thimble was 0.6 per cent of the total collected; the efficiency of the bag was therefore 99.4 per cent.

DISCUSSION OF OBSERVATIONS

Condition of Slag in Hearth

Strip-Mine Coal in Boiler No. 4. The ash which collected on the hearth of the furnace when burning this coal was in the form of a thinly fluid slag and was tapped without difficulty under all observed conditions of operation from a rate of steaming of 140,000 to 250,000 lb. per hour. The top of the bed had a smooth, fluid appearance, and slight ripples could often be seen as the flame swept across it.

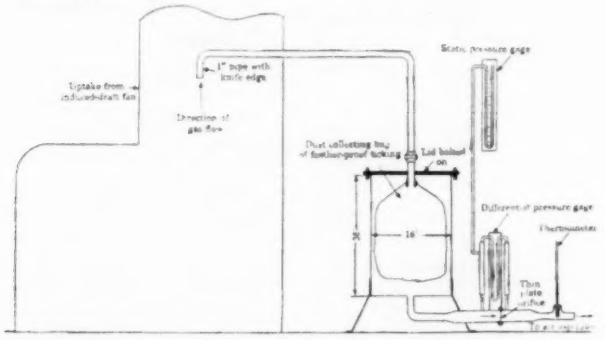

Fig. 8 Assembly of Apparatus for Sampling Flue Dust in Stack, Toronto Station

When the slag bed was cold after the boiler had been out of service for several days, the slag was not usually tapped until the second day of operation; difficulty was sometimes encountered at the first tappings until the solid slag in the corner at the tap hole had melted. Under normal operating conditions the slag became thinly fluid in that corner to the side and front walls, and only 5 to 15 minutes of work was necessary to open the tap hole and start the flow of slag.

Although the stream of slag tended to freeze over in the spout, an occasional pull with a rod removed the crust and kept the slag flowing freely. On some occasions, when too large a hole had been opened in tapping or when the slag level was high, the rate of flow became greater than the jets of water could cool and carry away, and it was necessary to decrease the size of the stream by spraying it with water.

Pittsburgh Coal in Boiler No. 4. Both periods of the burning of Pittsburgh coal followed periods when the boiler was out of service for several days, and were therefore started with a cold slag bed remaining from the burning of strip-mine coal. During each run, slag was tapped from the furnace on the first trial, the second day after the start, but thereafter the slag became hard in the bed near the tap hole and a hole was broken back to where it was fluid enough to run, only with a great deal of labor. The boiler load was increased, the excess air was decreased, air hammers were used, wood fires were built in the tap hole to prevent chilling of the slag by the cold air drawn in, and the combined efforts of several men were required almost continuously during the daytime to start and maintain the flow of slag.

The bed did not present the smooth appearance which it had when burning the strip-mine coal; it was rough and filled with small pieces of unfused ash. Feeling with a rod showed that there was molten slag in the center of the furnace, but toward the walls it was not thin enough to flow. The first run with this coal was closed because of the failure of a portion of the furnace arch. Inspection of the furnace showed that there was an accumulation of unfused and partly fused ash in the back of the furnace to a depth of 5 to 6 ft. This did not occur when burning the coal the second time, although the slag was not more fluid. The second run was closed because the operators decided that they could not tap the slag without excessive labor. They felt, however, that they could have removed the slag if the tap hole had been in the side of the furnace in a hotter zone.

Pittsburgh Coal in Boiler No. 5. As this boiler had been out of service for repairs before the test, a mixture of Pittsburgh and strip-mine coal was fired for two days to insure the favorable condition of a fluid bed of slag before firing Pittsburgh coal only. During the 8 days' run the slag was fluid and was tapped without difficulty, except on the fourth day, when no attempt had been made to tap the slag for two days over a week-end. The slag appeared to be fluid enough to run in the center of the bed, but was hard at the walls and around the tap hole. The furnace temperature was raised by decreasing the excess air and in a few hours the slag had melted at the tap hole and was tapped easily. The test was closed because of the necessity of repairs to the superheater.

Georges Creek Coal in Boiler No. 4. Observations on the condition of the slag bed were made continuously from the start of the burning of this coal, which was fired after a period when strip-mine coal had been burned and the slag bed was thinly fluid. Within an hour and a half after the coal was started into the furnace a crust of sintered and unfused ash had formed on the surface of the bed. This increased in thickness, and several hours after the start it could scarcely be penetrated with a rod. A small amount of slag was tapped from the furnace on the first day of the run which was, presumably, the slag remaining from the strip-mine coal. After the first day the bed was solid at any point that could be reached with a rod and no more slag was tapped during the remaining three days in which the 900 tons of this coal available were burned.

The bed was very rough on top and much of the ash was unfused; it was slightly sticky at times but never fluid.

Mixtures of Coals. Although no extended observations were made with definite mixtures of coals, the change-over periods from the Pittsburgh and Georges Creek coals to the strip-mine coal in boiler No. 4 were observed. Each time, the top of the slag bed became fluid within a few hours after the change, and a successful tapping could be made within 8 to 12 hours.

The furnace was also seen under normal operating conditions when indeterminate mixtures of the Pittsburgh and strip-mine coals were burned. The operators reported no particular difficulty with tapping of slag with any normal mixtures of coals.

Temperature of Slag

Table 2 is a summary of the temperatures measured in the flowing slag in the spout and in the slag in the bed of boilers Nos. 4 and 5.

TABLE 2 SUMMARY OF TEMPERATURES IN SLAG

	Slag in spout			Slag in bed		
	Min.	Avg.	Max.	Min.	Avg.	Max.

		Boiler No. 5				
Pittsburgh.....	2400	2510_3	2725	2460	2570_3	2680

Note: Subscript following average temperature denotes number of determinations averaged.

[a] Slag not fluid. Temperature of top of bed.

In boiler No. 4 the minimum temperature measured in the flowing slag was 125 deg. lower with the Pittsburgh coal than with the strip-mine coal, but the average and maximum temperatures were practically the same. As the slag did not flow when burning the Georges Creek coal, temperature measurements could not be made in the spout.

The maximum temperatures measured in the slag bed of boiler No. 4 were very nearly the same when burning the three coals. The average temperature in the bed of the strip-mine coal slag was about the same as with the Pittsburgh, and 170 deg. higher than for the Georges Creek coal. As the slag was not actually fluid when burning the Georges Creek coal, the thermocouple tube could only be placed on the slag and not in it, consequently the temperatures recorded are not as accurate as those for the other coals.

In boiler No. 5 the average temperature of the slag flowing in the spout was somewhat lower and the maximum temperature was somewhat higher than in boiler No. 4. The average temperature measured in the slag near the tap hole in the bed of boiler No. 5 was higher than when burning Pittsburgh coal in boiler No. 4; both the average and maximum temperatures were nearly the same as those in the bed of strip-mine coal slag in boiler No. 4.

ging bottom was installed. Similar data were not taken on boiler No. 5.

There was considerable variation among the determinations made at similar ratings of the percentage of ash carried by the gases below the boiler tubes. This would be expected because the area of the sampling tube was very small compared to the area of the furnace, and because the velocity and direction of gas flow varied from moment to moment. The agreement of the results of separate determinations at similar ratings of the percentage of ash carried in the gases at the stack was excellent.

Both the softening and fluid temperatures were similar for the several samples with each of the three coals, both below the tubes and in the stack. The softening temperatures of the samples from below the tubes were generally somewhat lower than of the samples from the stack, but the fluid temperatures of the samples were more nearly the same.

Amount of Dust in Gases

Table 3 gives the amount of ash, percentage of combustible, and fusion temperatures of samples of dust taken from the gases below the boiler tubes and in the stack at the discharge of the induced-draft fan for each of the three coals at three boiler loads on boiler No. 4 with the slagging bottom, and with a mixture of strip-mine and Pittsburgh coal on the same boiler before the slag-

Fig. 9 shows graphically the values for the percentage of ash fired, carried in the stack gases, and for the percentage heat loss in carbon in the dust as taken from Table 3. The relative position of the curves for the boiler with the slagging bottom conforms with the relative fluid temperatures of the ash; the highest percentage of ash was carried out of the setting with the Georges Creek coal whose slag had the highest fluid temperature, and the lowest percentage of ash was carried out with the strip-mine coal whose slag had the lowest fluid temperature. The curve of the percentage of ash carried in the gases when the furnace had a dry bottom falls above all those with the slagging bottom. The coal burned when the samples were taken with the dry bottom was a mixture of Pittsburgh and strip-mine coals. The curve for a similar mixture with the slagging bottom would probably fall be-

tween the curves shown for the two coals. Hence the percentage of ash carried out with the slagging bottom would be approximately one-third, or 15 per cent of the total ash in the coal, less than with the dry bottom.

It is recognized that these values, even with the dry bottom, are lower than the usual values reported, but in view of the efficiency of filtering which was found and the excellent agreement of the results, they are reported with the belief that they are representative of the amount of ash carried at the point of sampling in the stack during normal operation. As the samples were taken from only one point in the stack, in the center, the results may possibly be low due to stratification; for the same reason the percentages carried by the gases below the boiler tubes may be high. A difference between the values at the two points would of course be expected because of deposition in the passes of the boiler. However, as the samples were taken at the same points for all three coals and for the dry and slagging bottoms, the relative results should be correct.

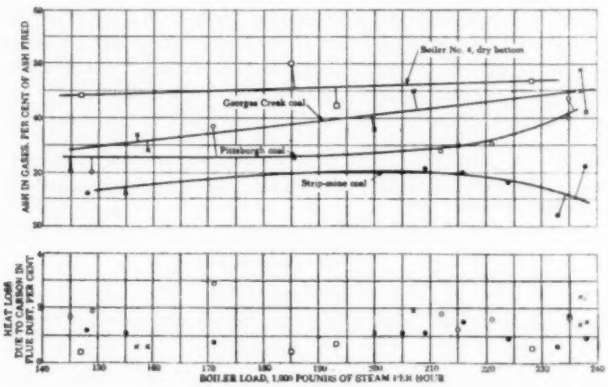

FIG. 9 PERCENTAGE OF ASH FIRED CARRIED OUT OF STACK WITH GASES AND PERCENTAGE HEAT LOSS IN CARBON IN DUST, BOILER NO. 4, TORONTO STATION

The heat loss in carbon in the dust which went out of the stack, for all samples but two, was less than 2 per cent. There appears to be no relation between this value and the coal or the rate of steaming. However, the average loss for the furnace with the dry bottom, shown by the squares in Fig. 9, was less than with the slagging bottom.

COMPOSITION OF ASH, SLAG, AND DUST

Table 4 gives the chemical analyses of the original ash, slag from the bed, and dust from below the boiler tubes and from the stack of the three coals tested in boiler No. 4 and of the coal ash and slags from boiler No. 5.

COMPOSITION OF SAMPLES FROM BOILER NO. 4

The analyses of the dusts were made on composites of two or three samples taken simultaneously at each point during the low-rate tests; the slag samples were taken from the top of the bed following the period of dust sampling, and the ash analyses were made on composites of two to four daily samples.

The outstanding difference in the composition of the three coal ashes was in their ferric oxide content. This was 23.8 per cent for the strip-mine ash with a fluid temperature of 2400 deg., 10.6 per cent for the Pittsburgh ash with a fluid temperature of 2640 deg., and 5.4 per cent for the Georges Creek ash with a fluid temperature of 2790 deg. The lime content of the strip-mine and Georges Creek ashes was approximately similar, but that of the Pittsburgh ash was much greater. The content of both the silica and alumina increased as the fluid temperature increased.

The ferric oxide content of the slag of all three coals was greater than that of the ash, by about one-sixth for the strip-mine coal, by almost one-half for the Pittsburgh coal, and by more than twice for the Georges Creek coal. The lime content of the slag did not change greatly from that of the ash for any of the coals. The softening temperature of the slag was lower than that of the ash for all three coals: it was lower by more than 300 deg. for the Georges Creek coal, but with this coal the fluid temperature of the slag was only 120 deg. lower than that of the ash; for the other two coals it was practically the same for the ash and slag.

The composition of the dust samples from the two positions was very similar for each coal, except that the silica content was 1.3 to 3.6 per cent higher in the dust from the stack than in that from below the tubes. With this exception the composition of all dust samples did not greatly differ from the composition of the coal ash, and the softening and fluid temperatures were also nearly the same as those of the coal ash.

COMPOSITION OF SAMPLES FROM BOILER NO. 5

The composition of the two samples of coal ash from this boiler was similar, but differed from that of the Pittsburgh coal ash from boiler No. 4 in that the alumina content was somewhat higher, the ferric oxide content lower, and the lime content higher. The softening temperatures of both samples and the average fluid temperature was lower than of those from boiler No. 4.

The increase in the ferric oxide content of the slag over that of the ash was greater than in boiler No. 4, but the percentage was very nearly the same. The softening temperatures of the slags were not much lower; but the fluid temperatures were lower than those of the coal ash, and also lower by about 100 deg. than that of

[a] Analysis of composite sample.

the slag from boiler No. 4, although the composition of the slags from the two boilers was nearly the same. The fluid temperatures of three other samples of slag from boiler No. 5 were 2420, 2490, and 2530 deg., which shows good agreement and confirms that the slag deposited from Pittsburgh coal on the bed of No. 5 boiler had a lower fluid temperature than that taken from the bed of No. 4.

Table 5 gives the composition of three additional samples of slag from the bed, two from the side-wall tubes, and one from the boiler tubes from boiler No. 4 when burning Pittsburgh coal. These analyses are very similar to those of the corresponding samples given in Table 4 for the same coal. In the samples from the bed the content of ferric oxide was higher than in the coal ash, whereas in the slag from the tubes it was nearly the same or somewhat less.

Combustible Content of Slag Samples

When ignited preparatory to chemical analysis, some of the samples of slag showed a gain in weight and others showed a loss. A gain on ignition results from the oxidation of ferrous or metallic iron in the slag, and loss may result from the burning out of combustible matter or from the decomposition of carbonates or sulphides. Samples which showed an appreciable loss on ignition were tested for carbonates or sulphides with negative results.

Because of the possibility of gain in weight due to the oxidation of iron or ferrous oxide the loss on ignition cannot be used as a measure of the combustible content of the slag; therefore it was determined by analysis for hydrogen and carbon, as in the ultimate analysis of coal, by combustion in oxygen and collection of the water and carbon dioxide formed.

[a] Sampled periodically over entire period of tapping.
[b] Gain on ignition.
[c] First half of tapping period.
[d] Last half of tapping period.

Table 6 gives the results of this determination on 14 samples. All contained carbon; the content varied from 0.3 to 8.6 per cent. The samples which contained the most carbon were slags from the Pittsburgh and Georges Creek coals burned in boiler No. 4. As previously noted, these slags were very viscous and probably enclosed particles of carbon. However, the strip-mine slag, which was very fluid, contained up to 4.7 per cent carbon, and sample No. 153, which was an average of an entire period of tapping, contained 2.7 per cent carbon.

No investigation has been made of the form in which the carbon is present in the slag. There is a possibility that it may be in solution in metallic iron which has been reduced from the oxide or silicon carbide may have been formed. In the larger percentages, however, it is considered probable that it is deposited on the surface of the slag bed as particles of coke and is possibly prevented from burning by being covered by slag. This conception is partly confirmed by samples 154 and 155. The sample representing the first half of the tapping period, which was, probably, principally the lower part of the molten slag, contained but 0.7 per cent carbon; the sample representing the last half of the period, which was probably the top of the slag bed, contained 4.6 per cent carbon.

The heat loss resulting from these percentages of carbon is not large. Assuming 10 per cent ash in the coal and 50 per cent of the ash fired collected as slag in the hearth, 3 per cent carbon in the slag would mean a loss of less than 0.2 per cent of the heat in the coal.

TABLE 7 COMPOSITION OF SLAG AT VARIOUS DEPTHS IN BED BOILER NO. 4

Sample No.	Depth of sample, in.	Per cent: Loss on ignition	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Initial deform. temp., deg.	Soft temp., deg.	Fluid temp., deg.

11	12–15	0.3[a]	40.2	22.9	33.3	2.6	1.5	1990	2040	2340

[a] Gain on ignition.

Not enough samples have been taken and analyzed to show the average percentage of carbon which may be in the slag, but the results do show that the molten slag may carry unburned carbon and that the possibility of loss cannot be ignored.

Composition of Slag at Various Depths in Bed

As previously stated, the hearths were made up of burned dolomite which was only loosely thrown in. During the early weeks of operation of the furnace the company's engineers observed that the slag contained material which appeared to be dolomite. It was also thought that a great deal of dolomite was probably chemically dissolved by the slag. Before the start of the present tests samples of slag were taken in boiler No. 4 at four depths in the bed remaining from the burning of strip-mine coal.

Table 7 gives the analyses of the four samples. The principal differences in the first three samples was the increase in the ferric oxide content and the corresponding decrease in silica with increase in distance from the top of the bed. The content of lime and magnesia by which the presence of dolomite may be detected was practically constant and normal for slag from that coal.

The fourth sample at 12 to 15 in. from the top contained more lime and magnesia than would come from the coal ash, and therefore there were traces of dolomite left at that depth.

Because of the uneven surface of the slag bed it was impossible to measure accurately the height of the top of the slag above the original level of the dolomite, but it was estimated to be 10 to 12

[a] Not including reading at 6 in.

in. During operation the slag level was not drained down to the depth at which the samples were taken, therefore the actual effective bottom was principally slag.

Temperature of Furnace Gases

Table 8 presents a summary of the temperatures measured in the gases in boiler No. 4 at the lower observation hole, which was approximately 4 ft. from the face of the burners. As no general temperature survey of the furnace was made these temperatures represent neither the maximum, minimum, nor average temperatures of the furnace gases.

TABLE 9 COMPARISON OF TEMPERATURES BELOW BOILER TUBES IN BOILER NO. 3 WITH DRY BOTTOM AND BOILER NO. 4 WITH SLAGGING BOTTOM, TORONTO STATION

	Boiler No. 3	4	3	4
Boiler load, 1000 lb. steam per hour	160	165	195	200

[a] By recording thermometer.
[b] Average of 4 determinations at each distance.

Visual observation of the flames with the three coals indicated that the flame of the Georges Creek coal, whose volatile content was 20 per cent, was longer than with the other two coals, whose volatile content was 35 to 37 per cent, when other furnace conditions were similar. The difference between the temperatures measured with the Pittsburgh and Georges Creek coals confirm this indication of difference in the length of the flame for with similar rating, excess air, and primary air pressure the temperatures were lower with the Georges Creek coal.

The principal, independently variable factor which governs the length of the flame is the pressure of the primary air. Fig. 10 shows the average temperature of the gases at 18 to 48 in. from the side wall at the lower observation hole and just below the tubes with different pressures of primary air when burning Georges Creek coal with a boiler load of approximately 210,000 lb. of steam per hour. All other conditions as furnace draft, boiler differential, and excess air were maintained as constant as possible. The increase in temperature near the burners shows that the length of flame decreased with the increase in air pressure. The corresponding decrease in temperature below the boiler tubes was due to the longer time that the gases had for transfer

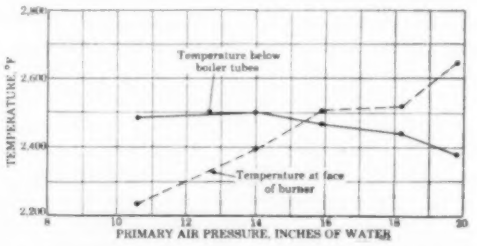

Fig. 10 Variation of Temperature at Face of Burner and Below Boiler Tubes With Pressure of Primary Air, Georges Creek Coal, Boiler Load Approximately 210,000 Lb. of Steam per Hr. Boiler No. 4, Toronto Station

of heat to the water-cooled surface after combustion was complete.

Comparison of Temperatures Below Tubes in Furnaces With Dry and Slagging Bottoms

Table 9 gives the temperature of the gases measured about 6 in. below the boiler tubes at similar loads and other conditions in boilers No. 3 and 4. The boilers and furnaces were exactly alike except that the slag hearth in No. 4 covered the lower water-tube slag screen. The area of radiant-heat absorbing surface was therefore approximately 166 sq. ft. less in No. 4 than in No. 3 boiler.

The average temperature below the tubes in No. 3 at a load of 160,000 lb. of steam per hour and 11.9 per cent CO_2 at the stack was 395 deg. lower than in No. 4 at a load of 165,000 lb. per hour, and 12.0 per cent CO_2. The temperature was 295 deg. lower in No. 3 than in No. 4 at loads of 195,000 and 200,000 lb. per hour, when the percentages of CO_2 were 11.9 and 12.1, respectively. These temperature differences of 395 and 295 deg. has decreased

TABLE 10 PERCENTAGE COMPOSITION OF GASES NEAR SLAG BED, WHEN BURNING PITTSBURGH COAL, BOILER NO. 4

Boiler load	Boiler diff., in. of water	Furnace draft, in. of water	Feeder speed, r.p.m.	CO_2 by recorder, per cent	Primary press., in. of water	Per cent CO_2	O_2	CO	CH_4	H_2	N_2

to 10 and 27 deg. at the boiler outlet, and to 2 and 3 deg., respectively, at the air-heater outlet. Therefore, although the difference in gas temperature at the entrance to the boiler was relatively great, the heat-absorbing surface in the boiler and air heater was great enough so that the final efficiency of heat absorption in the two boilers was approximately the same.

Composition of Gases Near Slag Bed of Boiler No. 4

Only a few samples of gas were taken from the furnace as a complete survey of the gas composition was not considered within the scope of the investigation. Table 10 gives the composition of five samples taken in boiler No. 4 through the lower observation hole, 4 ft. from the front wall. To obtain an average sample the sampling tube was moved back and forth 12 to 40 in. from the side-wall tubes.

The composition of the samples taken varies considerably and

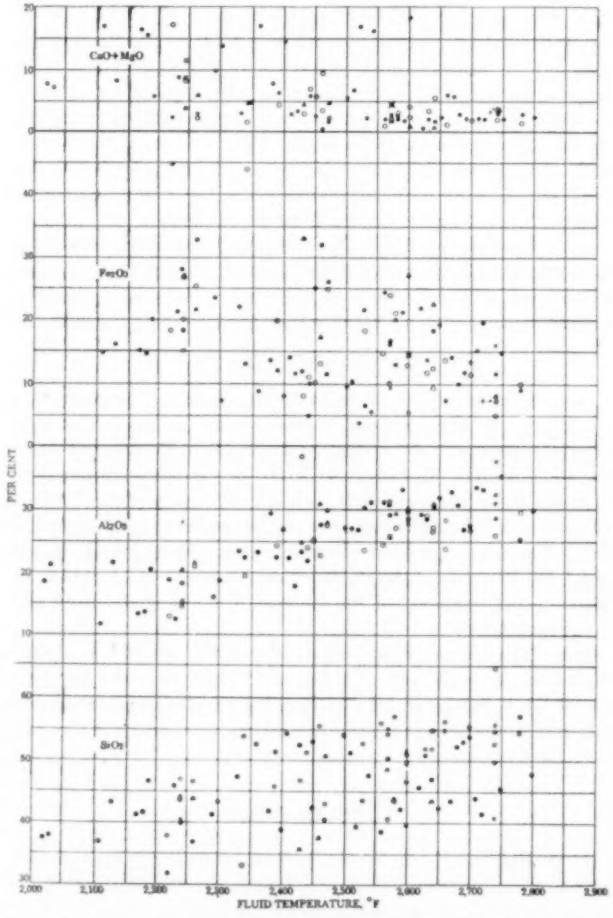

Fig. 11 Relation of Fluid Temperature of 120 Coal Ashes and Slags to Chemical Composition

not enough were taken to determine the average value. The presence of as much as 9.5 per cent of CO and 5.4 per cent H_2 in one sample and lower amounts in two other samples shows that the atmosphere over the hearth may be strongly reducing at times, which is advantageous in the formation of fluid slags from ash containing iron.

Addition of Fluxes to Coal Ash

The addition of fluxes has been suggested as a means to extend the advantages of the slagging method of removal of ash to include coals whose ash has a high fluid temperature.

Iron, lime, and the alkalis are the three fluxes that occur in the ash of coal in appreciable amounts. The quantity of alkalis in ash is not often determined; the data that are available show that the quantity of alkalis in the ash is less than in the coal, and that when coal is burned the greater part of the alkalis is carried away in the gases; the same action would be likely to occur if alkalis were added as fluxes to the coal, or bed of slag.

Iron and lime are the fluxes that are usually considered, but data relating them to the fusion temperatures of the mixtures are incomplete: a study of the silica-aluminum-iron-lime system is being made by the Bureau of Standards jointly with the Special Research Committee on Boiler-Furnace Refractories of the A.S.M.E.

TABLE 11 SOFTENING AND FLUID TEMPERATURES BY STANDARD CONE TEST OF MIXTURES OF PITTSBURGH COAL ASH AND SLAG WITH FERRIC OXIDE

Description of sample	Softening temperature, deg.	Fluid temperature, deg.
Original coal ash	2460	2560
Coal ash, fused at 2700 deg. for 30 min.	2280	2650
Fe_2O_3 mixed with coal ash, per cent:		
2.5	2390	2550
5.0	2350	2520
10.0	2240	2390
15.0	2260	2380
20.0	2230	2340
Coal ash mixed with Fe_2O_3 and fused at 2700 deg. for 30 min., per cent:		
2.5	2220	2650
5.0	2200	2570
Slag from bed	2340	2470
Slag mixed with 20 per cent Fe_2O_3	2020	2350
Slag mixed with 20 per cent Fe_2O_3 and fused at 2700 deg. for 30 min.	2100	2350

Attempts to derive relations from the analysis and fusion temperature of coal ash have not been successful because of undetermined factors or because the number of determinations is not enough. Fig. 11 shows such a plot of chemical composition against fluid temperature. The plot shows a general tendency for the Fe_2O_3 and the CaO + MgO to decrease with increasing temperature; plotting either the sum of these three fluxes or the ratio of the total acids to the total bases gives a somewhat better agreement, but neither method establishes a definite enough guide to determine the additional quantity of fluxes to add to assure the necessary reduction of the fluid temperature. As a rule, iron occurs in greater amount in the ashes with a low fluid temperature than does lime; high content of iron was the characteristic of the strip-mine coal used in this investigation.

A thorough investigation of the possibility and economical feasibility of adding flux to coal ash to render it fluid would necessitate a method of estimating the fluidity of the mixtures and many tests in laboratory and plant. However, the results of a brief study which has been made of the softening and fluid temperatures of mixtures of ferric oxide with Pittsburgh coal ash and slag by the standard gas-furnace cone test are of interest. The ash used was from a sample of the Pittsburgh coal obtained during these tests. One portion of it was fused at 2700 deg. for 30 minutes in a platinum crucible heated in a gas furnace, and the resultant slag was ground fine and a cone test made to determine whether the fusion temperature had been changed by the melting. Other portions of the ash were then mixed with increasing percentages of Fe_2O_3 and the fusion temperatures determined without previously fusing the mixture. In addition, two of these mixtures were fused at 2700 deg. for 30 minutes and the fusion temperatures of the slag determined.

Table 11 presents the results of this study. They show that fusion of the ash lowered the softening temperature but not the fluid temperature. Likewise the fluid temperatures of the fused mixtures of the ash or slag with the ferric oxide were not lower than those of the mixtures which were only ground together. Additions of 2.5 or 5 per cent of ferric oxide did not appreciably lower the fluid temperature of the ash; 10 per cent lowered it 170 deg. to 2390 deg. and further additions lowered it little more. The addition of 20 per cent ferric oxide to the slag lowered the fluid temperature from 2470 to 2350 deg.

These tests indicate that the addition of 10 per cent of ferric oxide to the ash might decrease the fluid temperature of the Pittsburgh coal ash enough to give a slag fluid enough to flow from the

furnace. As the coal contained approximately 10 per cent ash, and assuming 50 per cent of the ash was deposited on the hearth, 0.5 per cent or 10 lb. of ferric oxide per ton of coal or approximately 1600 lb. per furnace per day would be required. Ferric oxide is available in the form of iron ore which contains about 70 per cent ferric oxide or as mill scale.

More or less than this amount might be required, depending on the amount of the flux which was carried out with the gases, and the rate of combination and mixing with the ash on the hearth. It would be necessary to add the flux either continuously, or at regular intervals in proportion to the rate of firing coal. The mechanical means of adding the flux might offer some difficulty, but this feature will not be discussed in this paper.

SUMMARY OF OBSERVATIONS

As the data given in this paper are based on the burning of the three coals in furnaces which were not originally designed for use with a slagging bottom, the results of the observations cannot be generalized too freely, and it may be expected that the actual numerical values would be affected by the types of furnace and burners; on the other hand, the relative order of the actions should be the same. The unfavorable conditions for the removal of the slag from boiler No. 4 have been pointed out: the proportional area of the bed exposed to the cooling action of the walls was large, the position of the main part of the bed under the face of the burners was not favorable relative to the zone of maximum combustion, and the tap hole was in a corner where the cooling action was great and where a long tunnel was necessary.

1 A selective separation of the constituents of the ash occurred with all coals which increased the percentage of ferric oxide in the slag compared with that in the ash of the coal. The percentage increase was greater as the percentage of ferric oxide in the original ash was lower.

2 The softening temperatures of the slags were lower than those of the original ash, but the fluid temperature did not decrease as much; the decrease of these fusion temperatures increased as those of the original ash increased and was about 120 deg. for the fluid temperature of the Georges Creek ash.

3 The percentage of the total ash fired which passed to the stack with the slagging-bottom furnace increased with increase in fluid temperature of the original ash. The amount carried out of the furnace even at the highest rating and with the least fluid ash was less than 50 per cent of that fired.

4 For similar coals the percentage of ash which passed to the stack with the slagging-bottom furnace was approximately one-third less than with the dry-bottom furnace.

5 All samples of slag analyzed contained carbon, although not enough were tested to determine the average content. The percentage heat loss was small, but the possibility of loss by unburned carbon in the slag cannot be neglected.

6 Comparisons of the temperature of the gas below the boiler tubes in two furnaces exactly alike, except that one was equipped with a water-tube slag screen and ash-collecting hopper and the other with a slagging bottom installed above the slag-screen tubes, showed that the temperature, at similar boiler loads and excess air, was 300 to 400 deg. higher in the furnace with the slagging bottom. The temperatures at the outlets of the air heater were, however, nearly the same.

7 During these tests the slag from the ash of the Pittsburgh coal could not be successfully removed as molten slag from the furnace of boiler No. 4, although as high a temperature was attained in the bed of slag as with the coal from the strip-mine. It was, however, on the border line of successful removal and the operators felt that it could have been tapped if the tap hole had been in a more favorable position.

8 The removal of the molten slag was successful when burning Pittsburgh coal in boiler No. 5 and the reasons for this, as compared with the non-success in No. 4, apart from the more favorable position of the tap hole, were probably that there was a somewhat higher average temperature of the slag and also that the average fluid temperature of the slag was about 100 deg. lower.

9 The chemical composition of the slags of the Pittsburgh coal from the beds of No. 4 and No. 5 boilers were nearly the same, although those of the coals differed appreciably: data are not available to explain why the fusion temperatures of the two slags differed.

10 The slag of the Georges Creek coal could not be removed from the furnace of boiler No. 4. The top of the bed was hard and the temperatures measured were those near the surface; the maximum temperatures observed were as high as those in the molten slag of strip-mine and Pittsburgh coals, but the average was 150 deg. lower; the position of the bed near the front wall of the furnace was less favorable with the low volatile Georges Creek coal because its longer flame placed the zone of maximum intensity of combustion farther from the burners.

11 A brief study of fluxes for Pittsburgh coal ash showed that the addition of ferric oxide in an amount of 10 per cent of the slag deposited should lower the fluid temperature so that it could be successfully tapped as molten slag from the furnace investigated.

ACKNOWLEDGMENTS

The cooperation with Stevens & Wood, Inc., was carried on through P. B. Rice, general engineer, who, with A. Carnegie, superintendent of power, Pennsylvania-Ohio Power and Light Co., F. C. Beattie, chief engineer, C. H. Davis, efficiency engineer, P. Kelly, boiler-room engineer, and all employees of the Toronto station rendered every assistance in the conduct of the investigation. The dust samples in the stack were collected by L. A. Orr and J. W. Freeman of the efficiency department. C. L. Aldeman, assistant fuel engineer, of the Bureau, was engaged during part of the investigation.

The chemical analyses were made in the general analytical laboratory of the Bureau of Mines at Pittsburgh under the direction of W. A. Selvig, and the coal analyses and fusion temperature determinations in the coal-analysis laboratory under the direction of H. M. Cooper.

Discussion

JOHN BLIZARD.[14] In Table 9 the authors compare the temperatures of thermocouples just below the boiler tubes when operating with a water screen and with a slagging bottom. They show that with a slagging bottom these temperatures are from 300 to 400 deg. higher than they are with a water screen.

This difference in temperature is greater than might have been expected, and if these temperatures really represent the actual temperatures of the gases entering the boiler tubes, then the furnace with the water screen must be credited with absorbing the additional heat equivalent to the lower temperature. The lower temperature with the dry bottom may be of great practical importance, since it will render the ash less likely to slag the boiler tubes.

I should like to know whether there was any greater tendency to slag the tubes of the boiler with the slagging bottom, and if so, whether this tendency may not to some extent militate against the removal of the slag in liquid form.

Since the temperatures in the furnace are reduced by the extent, position, and shape of the heating surface in the furnace, it is important to know how the heating surface of the water walls and water screen were computed.

[14] Head, Research Department, Foster Wheeler Corporation, New York, N. Y. Mem. A.S.M.E.

There are several ways of computing this surface. Some regard the projected area as the best measure; others use the total area; and the computation of the equivalent surface of indirect surface such as cast-iron blocks or fins may be carried out in many ways.

In the chart in Fig. 9 the carbon loss from a furnace with bare tubes is seen to be small and does not change with the rate of combustion. Since this rate of combustion varied between 13,000 and 25,000 B.t.u. per cu. ft. per hour, these results should go far to allay the fears of a few who hesitate to install bare tubes in a furnace for moderate rates of heat liberation.

The paper is a notable contribution to the literature of the subject of boiler furnaces, and the authors may rest assured that users and designers of powdered-coal furnaces will find their work of great value.

W. S. Johnston.[15] From the time the Toronto station went into initial operation until early in 1928, the ash from the pulverized-coal-fired furnaces was removed in the dry state by means of the conventional ash hoppers and hydraulic jets commonly used for such purposes. During that period there were four furnaces of the Lopulco design, and in October, 1927, two Bailey furnaces were added to the station. When the hopper-bottom type Bailey furnaces were fired with strip-mine coal some difficulty was experienced with accumulations of slag along the sides and tops of the hopper walls. The accumulation of slag greatly increased when Pittsburgh coal was fired, and could not be completely removed by the suggested method of increasing the furnace temperature by decreasing the excess air, increasing the CO_2, and thus fuse and melt the slag. With six boiler units in the plant there was a large amount of expensive manual handling of slag and ashes.

In the spring of 1928 it was decided to try a molten-slag bottom in the furnace of boiler No. 5, then fired with Calumet inter-tube burners, because of the reputed greater ease in tapping molten slag than in handling dry ash. This facility was very quickly established after one month's operation. A similar bottom was projected for boiler No. 4, being placed directly over the original floor-screen tubes, to determine (1) if slag could be melted and tapped from a furnace fired horizontally with bare furnace-wall tubes in front of refractory walls on three sides and (2) the effect of a molten-slag bed in contact with a refractory wall on the fourth side without any cooling protection.

The foregoing briefly outlines the reasons for changing to molten-slag furnace bottoms. Some troubles were encountered before the operators learned by experience exactly the correct method of handling molten slag. But the amount of labor required for disposing of refuse material was greatly decreased. What follows is offered, not as a criticism of the paper, but as supplementary comments which may convey some additional information to those interested in the subject.

When the flat bottoms were first installed at Toronto, there was not much information available as to how they should be constructed. It was assumed that a fluid-tight bottom carried on a heavy steel structure, because of the weight of the slag, would be necessary, and that it must be suitably lined with refractory material. Some diligence was used to secure a seal around the edges of the bottom adjacent to the furnace walls. The first bottom installed was lined with two courses of firebrick on top of a $^1/_2$-in. steel plate. When the second bottom was built, the lower course of firebrick was replaced by one course of sil-o-cel. In furnace No. 5 the steelwork was located above the original hopper bottom which closed it in on the front and back. The original brick walls of the ash hopper closed in the sides. This placed the supporting structure in a hot location that could not be ventilated. An attempt was made to take its temperature and it was found to run about 600 deg. None of the steel, though, was found to be seriously affected. In the light of experience it is believed that the insulating material, while desirable, is not essential.

Dolomite was placed on top of the brick. However, there is evidence that the molten slag has probably entirely melted the dolomite and may have melted some of the firebrick. What probably has occurred is that at some point in the furnace bottom a plane of equilibrium has been established. Below this plane the room air chills the slag below its melting temperature, and above the plane the slag begins to take the fluid state. Of course, initially it is necessary to provide refractory material, but after a period of operation the slag makes its own bottom which is practically impervious.

The location of the slag tap hole is of importance. On furnace No. 5 there was opportunity to place the hole wherever it was desired, and, more or less arbitrarily, it was located on the center line of a side wall. However, in the case of furnace No. 4, with its solid brick walls and water-cooled tubes on three sides, it was thought easiest, from the construction standpoint, to locate the tap hole in the solid brick front wall. Experience over a number of months indicated that the slag cooled somewhat below its fluid temperature by flowing through an 18-in. brick wall and over a brick-lined spout and impeded, at least, the initial tapping.

Considerable of the difficulty mentioned under the head of "Pittsburgh Coal in Boiler No. 4," in the paper by Ralph A. Sherman, P. Nicholls, and Edmund Taylor, was largely due to this fact. Within the last few months the location of the slag tap hole on this boiler has been changed to the south side of the furnace in place of the third side-wall water tube from the front which has been removed. The hole is at a much hotter point of the furnace, and it is now very easy to draw off the slag. In fact slag from Pittsburgh coal is tapped with almost the same facility as when strip-mine coal is fired. Probably the best material for a slag spout is cast iron; the slag does not stick to it, and it minimizes the cooling effect which results if the flow of slag down the spout is choked. The use of some kind of a gate at the outer end of the spout is highly desirable as it gives the operators a ready means of controlling the flow. A gate will not be frozen in place even though it is used to stop a flow of molten slag. Apparently the slag does not adhere to the iron or steel. In Mr. Cushing's paper it is mentioned that it is very easy to remove any solidified slag in the spout. This is true. It would seem to the inexperienced that this presents some difficulties, but actually it does not.

As soon as the slag leaves its bed, it must be moved to the water sprays as quickly as possible and kept at as high a temperature as is feasible. When the slag meets the water, two changes take place. The slag is cooled, and in the cooling process it is disintegrated. Thereafter, additional water continues the cooling process, carries disintegration further, and keeps the slag moving. Nozzles for the bottoms of chutes should be located so that the spray of water sweeps the surface of the bottom. This means a distance of but $^1/_4$ or $^1/_2$ in. and not 1 in. or more, as otherwise the slag will deposit and accumulate on the bottom below the sheet of water. Without a doubt, disposal of the refuse from a pulverized-coal-fired furnace may be easily accomplished in the molten state, but the degree of success depends upon, and is a direct function of, the fluid temperature of the slag.

If the ash is removed in the dry form through the conventional ash hoppers and hydraulic jets, only a portion of the total accumulation is removed each day, and finally the boiler units must be taken off the line for a thorough cleaning. On the other

[15] Engineer, Stevens & Wood, New York, N. Y. Mem. A.S.M.E.

hand, it is possible and practical with molten-slag removal to withdraw all of the slag accumulating over any period, provided it will flow, and it is not necessary to take a unit out of service for a general cleaning because of the slag in the furnace bottom. It has been found that molten slag can be handled at the rate of 7000 lb. or 35 cu. ft. in an interval of 10 minutes. As the accumulation at Toronto never exceeds about 20 tons, all of the slag may be removed within an hour. The average daily accumulation is between 4 and 5 in., and hence it requires only about three-quarters of an hour each day to remove the molten slag from one furnace.

Mr. Sherman's paper brings out the fact that the average temperatures of the slag beds from strip-mine and Pittsburgh coals were only about 170 deg. higher than for the Georges Greek coal. While the fluid temperature of the slag from strip-mine coal and Pittsburgh coal may be nearly the same, yet the viscosity of the Pittsburgh coal slag is higher than that from strip-mine coal, so that the latter does not flow quite as easily as the former. However, it does bring out the fact that possibly Pittsburgh coal slag has a fluid temperature very near the critical, i.e., its temperature is about the limit at which flow will occur.

One of the most interesting facts developed by the Bureau of Mines tests is the amount of ash discharged to the stacks. Prior to the tests, no accurate determination was made at Toronto of the amount disposed of in this way, but it was presumed to be at least two-thirds of the total ash. The tests indicate that it amounts to only about one-half of this quantity, or one-third of the total ash fired. It is interesting to note that the quantity of ash increased as better coal was burned, and it would be well if this subject were investigated further to confirm this conclusion.

When slag bottoms were first installed at Toronto, it was presumed the carbon loss in the ash would be greatly decreased. When the first slag was analyzed, only a trace of unburnt carbon was found. It is a considerable surprise that the Bureau tests show that there is some carbon in the slag, as a large number of slag analyses have shown that only a trace is present.

The addition of fluxes to the slag bed in order to make it flow and to decrease its fluid temperature partially solves a problem. From the figures given in the Sherman paper, it would seem as though a large quantity of flux must be used. With an all-water-cooled furnace without doors immediately above the bottom, it is likely to prove difficult to introduce the flux. One of the most desirable features to incorporate in the design of an all-water-cooled furnace with a molten slag bottom is a suitable access door in the lower part of the furnace, and thus avoid the necessity of entering the furnace above the wall tubes. Light ladders are available, but these are not as desirable as a door located near the bottom of the furnace or just above the slag floor. However, for an all-water-cooled furnace, the manufacturers of such equipment do not yet seem to be in a position to offer a suitable door.

R. M. HARDGROVE.[16] The authors have presented some very valuable data on the operation of slag-tap furnaces at Toronto, and are to be congratulated on the very thorough manner in which they have conducted these tests.

That traces of carbon were found in the slag is not to be wondered at, for it is always the last trace of any element that is difficult to eliminate in any chemical reaction.

A study of the ash from underfeed stokers shows carbon in the hard, vitrified pieces of slag as indicated by the first three items of Table 12, each group containing an average of over one per cent carbon as determined in the combustion train, and we might expect traces of carbon in the slag from slag-tap furnaces. However, it is usually only a trace, and if the authors are to be criticized at all, it will be because they have left the impression that the average carbon content in daily operation is as high as the few samples tabulated in the paper.

In Table 12 are given the average determinations of 49 samples from Toronto, 27 from Buffalo, and 3 from Oklahoma Gas and Electric, all taken during regular daily operation. The average carbon content for Toronto was 0.161 per cent and for Buffalo was 0.080 per cent. The samples marked "Ladle" were caught in a ladle as the slag came from the spout, while those marked "Sluice" were disintegrated slag caught from the sluice during the entire tapping period and then quartered down. The "sluice" samples are therefore more representative and in both plants average lower than the "ladle" samples.

The highest carbon content in any of the 79 samples tested was 1.25 per cent, so that a carbon content under 0.2 per cent can be expected under regular daily operating conditions.

Most samples gain in weight due to a change from Fe and FeO to Fe_2O_3 as mentioned in the paper, and this gain is roughly proportional to the iron content. The samples quoted in Table 12 have the following iron content:

	Toronto	Okla. Gas	Buffalo
Iron as Fe_2O_3	13.46	16.63	34.73
Avg. gain in weight plus carbon, per cent	0.875	0.697	1.44

The gains in each case are less than the theoretical change from FeO to Fe_2O_3, but more than the theoretical change from Fe_3O_4 to Fe_2O_3, which indicates that the iron exists partly as FeO and partly as Fe_3O_4, with some metallic iron Fe in the slag as tapped.

This method of ash removal can therefore be depended upon to give a loss of carbon in the ash at least as low as the best forms of dry ash removal from pulverized-fuel furnaces, and usually much lower.

The small percentage of ash passing up the stack as given in Table 3 of the paper is very remarkable, which bears out the writer's experience on other installations where the slag removed was measured and the quantity passing up the stack was found

[16] Research Engineer, Fuller Lehigh Co., Fullerton, Pa.

to be materially less than on installations using a form of dry ash removal. This result is also influenced by the character of the walls, as a refractory-covered surface giving a wet coat of slag will entrain more of the ash than a cold, dry surface.

Authors' Closure

In answer to Mr. Blizard's question, the area of the heating surface in the furnace was computed as the projected exposed area of the tubes.

The tendency to slag the tubes of the boiler was greater in both of the furnaces with slagging bottoms than in the furnaces with dry bottoms. It must be remembered, however, that these two furnaces were not originally designed for slagging operation; in furnaces which are designed with slagging bottoms the amount of radiant heat-absorbing surface in the furnace can and must be increased in order that the temperature of the gases entering the tubes will be lowered enough to prevent slagging of the tubes of the boiler.

Mr. Johnston has added some interesting and valuable comments on the history of and operating experience with the slagging furnaces at Toronto. The designing and operating engineers at this station deserve much credit for their work in applying this method of ash removal to other types of furnaces and coals than those which had previously been attempted.

Mr. Hardgrove has contributed some valuable additional data relative to the carbon content of slag from this type of furnace. The authors did not intend to convey the impression that the carbon loss might be as high in daily operation as the highest samples reported; for, as stated, not enough samples had been taken to show the average percentage of carbon which might be in the slag. The conclusion which was drawn was that, as all the 14 samples analyzed contained carbon, the possibility of loss could not be ignored although it would be expected to be low. Mr. Hardgrove's contribution of the analyses of these 79 samples is therefore very helpful, and his data confirm the expectation that the average carbon loss should be almost negligible.

FSP-51-52

Design of Steam Piping to Care for Expansion

By W. H. SHIPMAN,[1] SYRACUSE, N. Y.

This paper endeavors (1) to arrive at the fundamental principles of design, (2) to present a complete mathematical theory of piping subjected to expansion, and (3) to reduce the very complicated results to a simple, usable basis.

The mathematical analysis of expansion stresses and reactions is presented for discussion as the basis of a proposed code of practice for the design of steam piping. The mathematical analysis is verified by experimental work, part of which has been previously published, and part of which is original. Further check by experiment is desirable, and the cooperation of other engineers is requested in building up an absolutely dependable body of data upon which a code of practice may be based.

A STUDY of the flexibility of piping is important:

1 To avoid excessive moments at the joints which would damage the joints and cause leaks.

2 To avoid excessive reactions which would damage anchors and apparatus.

3 To avoid excessive stresses in the pipe.

Present methods of design consist largely of empirical rules and judgment of the designer as to the looks of the layout. Long experience with moderate pressures and temperatures has developed designers who can tell by the eye alone whether or not a given pipe line is sufficiently flexible. The higher temperatures now in use and the heavier pipe walls used with higher pressures have rendered this method of design highly untrustworthy. The following study was undertaken to reduce the subject, so far as practical, to a rational basis.

PART I—FUNDAMENTAL PRINCIPLES TO BE CONSIDERED IN DESIGN

Eight fundamental principles of design are here proposed, and elaborated throughout the paper. Although many of these principles may appear axiomatic to the practical designer, the literature reveals no previous mention of them as such.

Principle No. 1—Entire Pipe Line the Expansion Bend. As far as possible avoid expansion bends and design the entire pipe line to take care of its own expansion. Where the shape required to clear obstructions does not give sufficient flexibility it is true that more pipe must be added, but it does not follow that conventional bends are always the best solution. The rule should be to put all parts of the entire pipe line to work taking the expansion. The use of expansion bends should be the exception.

Principle No. 2—Supports and Anchors. Stresses and reactions are always increased by restraint from free movement. The secret of obtaining maximum flexibility lies in computing or estimating the shape of the pipe line after expansion, and then placing the supports (and anchors when possible) so that they will not interfere with this natural movement. Formulas are given for computing the movement of all points in the line.

Principle No. 3—Shape Efficiency. That shape is most efficient in which the maximum length is working at the maximum safe stress. See Fig. 22 for typical study. The application of this principle is limited somewhat by Principle No. 4 in that a less efficient shape will sometimes keep the joints away from points of high moment.

Principle No. 4—Moment at Joints. Excessive bending moment at joints is more likely to cause trouble than excessive stresses in pipe walls. This is witnessed by the fact that failures of pipe walls are rare while joints leak by the thousand, every new power plant having some leaky joints until the piping has set. This statement holds only for A.E.S.C. Standard piping and joints. It would be possible to put in more bolt area and stiffer flanges until the critical point would be pipe wall rather than joints.

Principle No. 5—Cold Springing. Piping should be designed with a reasonable amount of cold springing to facilitate erection, to reduce expansion stresses, and to reduce the distortion of the system. However, caution must be used where cold springing is relied upon to take care of expansion since there is always danger that the piping may grow or slide through anchorages, or that the joints may rotate under the effect of torsion, or that the amount of cold springing actually obtained may be far less than was expected.

Principle No. 6—Flattening of Curved Portions. Reactions and stresses are greatly influenced by flattening of the cross-section of curved portions of the pipe line.

Principle No. 7—End Conditions. Reactions and stresses are very greatly influenced by end conditions. A method of taking account of this factor is presented.

Principle No. 8—Variation of Physical Properties With Temperature. Working stresses should decrease with increasing temperature. Modulus of elasticity E decreases with temperature; mean coefficient of expansion α increases with temperature; and, within the range from 0 to 750 deg. fahr., the product αE is approximately constant for low carbon steel at the value 190 lb. per sq. in. per deg. fahr.

PART II—SURVEY OF PUBLISHED WORK

The following abstracts of the best-known works on piping published during the last twenty years show a rapid development of the subject. The abstracts are arranged in order of date of publication, and the most significant contributions are indicated in each case. Marbec, Lorenz, and Carlier do not seem to have been used by the other American writers on the subject.

(*A*) Bantlin, Prof. A., "Formänderung und Beanspruchung federnder Ausgleichröhren," *Zeit. V.D.I.*, vol. 54, no. 2, 1910, pp. 43–49. Prof. Bantlin found on tests of several thin-walled, short-radius, lyre-type bends made of seamless steel tubing that the flexibility of the bends was as much as five times that indicated by the common theory for solid curved bars. Bantlin found no such discrepancy for a cast-iron bend, and suggested that the discrepancy for steel tubes might be due to wrinkles and irregularities produced in the manufacturing process. References (*B*), (*C*), (*D*), (*G*), (*J*), (*K*) and the present work account for this discrepancy on another basis.

(*B*) von Karman, Dr. Th., "Über die Formänderung dünnwandiger Rohre," *Zeit. V.D.I.*, vol. 55, 1911, p. 1889. Dr. von Karman developed formulas which showed that the dis-

[1] The Atmospheric Nitrogen Corporation.

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., Dec. 3 to 7, 1928, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

crepancies observed by Prof. Bantlin were explainable by a theory which considered the effect of flattening of the cross-section on the stress distribution and flexibility. The flattening referred to is that produced by bending due to expansion and not that produced by the manufacture of the bend. Karman's analysis employed the theory of least work under the assumption that the mean circumference of the pipe remains unchanged during the deformation of the cross-section.

(*C*) Marbec, M., *Bulletin Association Technique Maritime*, vol. 22, 1911. Marbec developed by the method of least work a formula for the relative flexibility of straight and curved pipes under the assumption that the deformed cross-section takes the shape of an ellipse.

(*D*) Lorenz, Prof. H., "Die Biegung Krummer Rohre," *Dinglers Polytechnisches Journal*, Sept. 14, 1912, p. 577. Prof. Lorenz developed, by an application of Castigliano's theorem, a formula for the relative flexibility of straight and curved pipes, under the assumption that the deformed cross-section is doubly symmetrical, making no assumption as to the form of the curve.

(*E*) Crane Company, "Pipe Bends, Their Growing Use and Efficiency," *The Valve World*, Oct., 1915. This report gave the results of extensive tests on full-size pipe bends. The design data, proposed as a result of these tests, differs materially from more recent data (see Fig. 15), but is often quoted in catalogs and handbooks and is widely used by engineers.

(*F*) Crocker, S., and Sanford, S. S., "The Elasticity of Pipe Bends," MECHANICAL ENGINEERING, 1922, p. 547. This work was a distinct step in the solution of the problem, and gave many mathematical solutions with check tests. Though it is stated that one end is assumed free, an analysis shows that both ends of all symmetrical bends were treated as if free. The stresses and reactions are considerably greater than commonly believed, but are still too small, as the author himself points out in a later article (reference *H*), because in practice pipe ends are more nearly fixed than free.

(*G*) Carlier, Henri, "L'Aptitude elastique des tuyauteries a vapeur au point de vue dilatation," 1920, 1923, 1925, 1927. (Copies obtainable from author, Ingenieur, Ressaix (Hainaut) Belgium.) The first three publications contained detailed solutions, by the free-body method, of many complicated single-plane shapes, all with both ends fixed, and with a flexibility factor *K* used in connection with all curved members. The fourth publication covered a typical two-plane shape. These works represent the most complete mathematical treatise published to date on pipe expansion.

(*H*) Crocker, S., "How to Lay Out Power Plant Piping—V," *Power*, Aug. 3, 1926, p. 172. In this article the author stated that even the high values given in his previous paper (reference *F*) are too low, so that data widely published in handbooks and catalogs are even farther from the true conditions. For example, the maximum bending stress in a U-bend is 1.5 times that previously published (Par. *F*), and the thrust is 3 times as great.

(*J*) Hovgaard, Wm., "The Elastic Deformation of Pipe Bends," *Jour. Math. and Phys.*, vol. 6, no. 2, Nov., 1926, pp. 69–118. In addition to illustrating a graphical method of computing thrust and moment for certain hinged-end bends, Hovgaard, independently derived Karman's equation for the relative flexibility of curved and straight pipes, and showed that four of the five full-size pipe bend tests considered verified Karman's equation almost exactly, while the fifth bend was about 20 per cent more flexible.

(*K*) Wahl, A. M., "Stresses and Reactions in Expansion Pipe Bends," Trans. A.S.M.E., 1928, FSP-50-49. Wahl derived formulas by Castigliano and free-body methods for reactions and moments for several single-plane pipe bends under various combinations of end conditions, and showed that these formulas, using Karman's flexibility factor *K*, are checked by several experiments on small model U-bends. One of the most useful parts of the paper is a chart for determining the maximum resultant stress (using Karman's analysis and the Guest or shear theory of failure) in terms of the conventionally computed maximum bending stress.

PART III—THEORETICAL ANALYSIS

A—Introduction

The determination of deflections, moments, reactions, and stresses in pipe lines by ordinary mathematical methods is tedious and requires a working knowledge of integral calculus and the use of much algebra. The methods herein developed facilitate the computation of the required unknown quantities for pipe lines in one plane, and by eliminating calculus operations, make the solution depend on substitution in formulas only. With the assistance of curve sheets as illustrated under Part V, the work may be greatly simplified and shortened.

It has been impossible to include complete derivations of formulas but the author will be glad to supply these upon request.

B—Notation

A, B, C, F, G, H = values of integrals given in Table 1
a, b, c, d, e, f, g = distances on pipe sketches
0, 1, 2, 3, 4, 5, 6, 7, 8, etc. = points on pipe line
A_o = area, sq. in.
D = outside diameter of pipe, in.
E = modulus of elasticity, lb. per sq. in.
F_x = horizontal force, lb.
F_y = vertical force, lb.
h = vertical projection of pipe line between anchors, in.
I = moment of inertia, quartic in.
K = relative flexibility of curved and straight pipes (see Part III, J).
L = horizontal projection of pipe line between anchors, in.
M = bending moment at any point on the pipe, in-lb.
M_0 = moment reaction at left-hand end of any one-plane pipe line
M_1 = moment reaction at right-hand end of any one-plane pipe line
N = ratio of dimensions of geometrically similar pipe lines
P = vertical force at any point on a pipe line, lb.
p = any point on a pipe line
Q = horizontal force at any point on a pipe line, lb.
R = radius of center line of pipe bend, in.
r = mean radius of cross-section of pipe, in.
s = distance along center line of pipe, in.
S_t = tensile stress, lb. per sq. in.
S_s = shearing stress, lb. per sq. in.
T = temperature rise, deg. fahr.
t = thickness of pipe wall, in.
U = elastic energy, in-lb.
V = $\sqrt{(F_x^2 + F_y^2)}$
x, y, z = coordinates of any point on pipe line, in. Left end of pipe line is origin unless otherwise specified
α = mean coefficient of linear thermal expansion, in. per in. per deg. fahr.
β = ratio of the maximum resultant stress in pipe to the commonly computed bending stress (see Fig. 19 and Part III, J and K).
Δ = deflection, in.
Δx = x-component of deflection, in.
Δy = y-component of deflection, in.
η = factor depending on shape of pipe line
θ, ϕ = angles shown in pipe sketches

λ = factor for curved pipes = $(tR)/r^2$
μ = factor depending upon radius of bend
π = 3.1416

C—Development of Fundamental Equations for Any One-Plane Pipe Line

The expression for the elastic energy is

$$U = \frac{K}{2EI}\int M^2 ds \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

Use of this expression involves the following assumptions:

1 Energy due to direct compression or tension is negligible.
2 Energy due to direct shear is negligible.
3 Neutral axis of cross-section is at center of gravity of cross-section.
4 Pipes originally curved are more flexible than pipes originally straight, and the relative flexibility K is a function only of the ratio tR/r^2.

An additional assumption will be needed later:

5 Moment at any point on a pipe line is not affected by deflections of the pipe line.

Let point p of Fig. 1 be any point, with coordinates x and y, of any one-plane pipe line between points 0 and 1. The reaction at each end may be represented by a force consisting of two components F_x and F_y, and a moment M_0 or M_1.

Equilibrium of the forces on the part $0p$ of the line gives for the moment M at any point.

$$M = M_0 + F_y x - F_x y \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

Moments will be considered positive when they act in a clockwise direction on the left-hand end of any portion or in a counterclockwise direction on the right-hand end as shown in Fig. 1

According to Castigliano's theorem, the components x and y

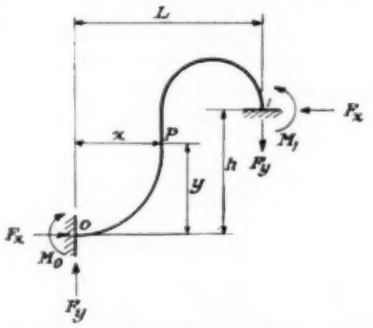

Fig. 1 Single-Plane Pipe Line Between Any Two Points 0 and 1

of the deflection of 0 relative to 1, and the angular deflection $\Delta\phi$ of the tangent to the elastic line at 0 relative to the tangent to the elastic line at 1 are given by the equations:

$$\Delta x = \frac{\partial U}{\partial F_x}; \quad \Delta y = \frac{\partial U}{\partial F_y}; \quad \Delta\phi = \frac{\partial U}{\partial M_0} \quad \ldots\ldots [3]$$

Substituting Equation [1] in Equations [3]

$$\Delta x = \frac{K}{2EI}\int 2M\frac{\partial M}{\partial F_x}ds$$

$$\Delta y = \frac{K}{2EI}\int 2M\frac{\partial M}{\partial F_y}ds$$

$$\Delta\phi = \frac{K}{2EI}\int 2M\frac{\partial M}{\partial M_0}ds \quad \ldots [4]$$

Differentiating M in Equation [2] with respect to F_x, F_y, and M_0,

$$\frac{\partial M}{\partial F_x} = -y; \quad \frac{\partial M}{\partial F_y} = x; \quad \frac{\partial M}{\partial M_0} = 1 \quad \ldots\ldots [5]$$

Substituting [5] in [4]

$$\Delta x = -\frac{K}{EI}\int My ds \qquad \Delta y = \frac{K}{EI}\int Mx ds$$

$$\Delta\phi = \frac{K}{EI}\int M ds \quad \ldots [6]$$

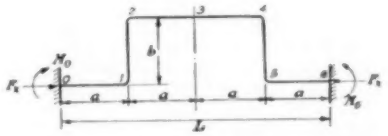

Fig. 2 Example of Use of Table 1

The values of F, G, and H for the symmetrical expansion bend shown in Fig. 2 may be obtained from Table 1 as follows:

Part of pipe		Value of F	Value of G	Value of H
0 to 1		0	0	a
1 to 2		$b^2/2$	$b^3/3$	b
2 to 3		ab	ab^2	a
3 to 4		ab	ab^2	a
4 to 5		$b^2/2$	$b^3/3$	b
5 to 6		0	0	a
Total	0 to 6	$2ab + b^2$	$2ab^2 + 2b^3/3$	$4a + 2b$

Substituting in general Equations [16] and [17] for symmetrical lines, and simplifying:

$$M_0 = \frac{EI\alpha TL}{2ab + b^2/3} \text{ and } F_x = \frac{EI\alpha TL}{ab^2 + b^3/6}$$

Equations [6] are fundamental for any one-plane pipe line with any condition of end fixedness. For most cases they are identical with those developed by a slightly different method by Carlier (reference G) and used throughout his work.

D—Development of General Equations for Any One-Plane Pipe Line With Fixed Ends

Since the tangents at the ends do not move, $\Delta\phi = 0$. Substituting Equation [2] in Equations [6]

$$\Delta x = -\frac{K}{EI}\left[M_0\int y ds - F_x\int y^2 ds + F_y\int xy ds\right] \quad \ldots\ldots [7]$$

$$\Delta y = +\frac{K}{EI}\left[M_0\int x ds - F_x\int xy ds + F_y\int x^2 ds\right] \quad \ldots\ldots [8]$$

$$\Delta\phi = 0 = \frac{K}{EI}\left[M_0\int ds - F_x\int y ds + F_y\int x ds\right] \quad \ldots\ldots [9]$$

Equations [7], [8], and [9] contain six different integrals. Each of these integrals multiplied by K may be represented by a single symbol, such as A, B, C, F, G, and H. For example, let $K\int x ds = A$. For any given pipe line consisting of several curved and straight parts joined together, $A = K\int x ds$ may be determined by integrating for the separate parts of the pipe line and adding the results algebraically.

Equations [7], [8], and [9] may be written:

$$\Delta x = -\frac{1}{EI}\left[M_0 F - F_x G + F_y B\right] \quad \ldots\ldots [10]$$

$$\Delta y = \frac{1}{EI}\left[M_0 A - F_x B + F_y C\right] \quad \ldots\ldots [11]$$

$$\Delta\phi = 0 = M_0 H - F_x F + F_y A \quad \ldots\ldots\ldots\ldots [12]$$

For simple circular arcs and straight pipes in one plane the values of A, B, C, F, G, and H are given in Table 1.

Solving Equations [10], [11], and [12] for M_0, F_x, and F_y and putting $\Delta x = \alpha T L$ and $\Delta y = \alpha T h$, where α = coefficient of expansion, T = temperature difference between hot and cold pipe line, and h and L are the vertical and horizontal distances shown in Fig. 1:

NOTE: Equations for shapes not given may be obtained by algebraic addition to those given. All measurements are from left-hand end of pipe line.

Table 1 has two fields of use:

1. For the original derivation of formulas similar to those given under Part V.
2. For solution of complicated special cases. See Part III, R for typical examples.

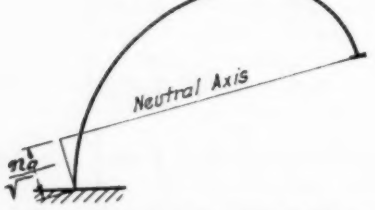

FIG. 3 POSITION OF NEUTRAL AXIS FOR PIPE LINE WITH RIGHT END HINGED AND LEFT END PARTIALLY FIXED

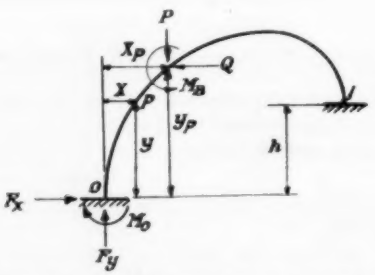

FIG. 4 PIPE LINE WITH FORCE AND MOMENT APPLIED BETWEEN THE ENDS

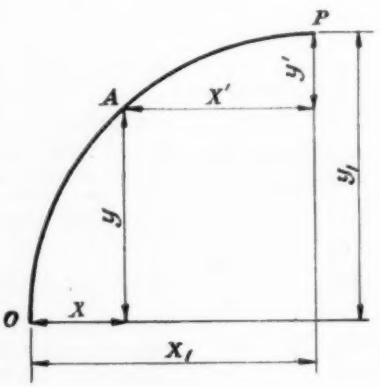

FIG. 5

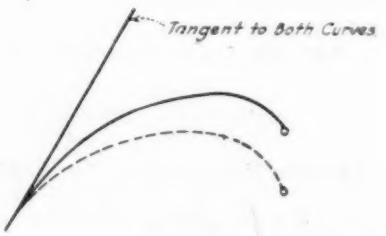

FIG. 6

$$M_0 = \frac{EI\alpha T[F(Bh + CL) - A(BL + Gh)]}{2ABF + HGC - A^2G - B^2H - CF^2} \quad [13]$$

$$F_x = \frac{EI\alpha T[H(Bh + CL) - A(AL + Fh)]}{2ABF + HGC - A^2G - B^2H - CF^2} \quad [14]$$

$$F_y = \frac{EI\alpha T[H(BL + Gh) - F(AL + Fh)]}{2ABF + HGC - A^2G - B^2H - CF^2} \quad [15]$$

For symmetrical lines with fixed ends $h = 0$, $F_y = 0$ and Equation [11] ceases to exist. Solving Equations [10] and [12] together, simpler expressions for M_0 and F_x involving only the integrals F, G, and H are obtained:

$$M_0 = \frac{EI\alpha TLF}{GH - F^2} \quad [16]$$

$$F_x = \frac{EI\alpha TLH}{GH - F^2} \quad [17]$$

For the special case of a symmetrical fixed-end line with center of gravity located a distance above the origin equal to half the maximum height of the line

$$M_0 = \frac{EI\alpha TLh'}{4G_c} \quad [18]$$

$$F_x = \frac{EI\alpha TL}{2G_c} \quad [19]$$

where h' = maximum height of bend
G_c = the integral G for the upper half of the bend, using the neutral axis as origin.

E—General Equations for Any One-Plane Pipe Line With Hinged Ends

In this case, the resultant thrust always passes through the hinges, and $M_0 = 0$

$$F_x = \frac{EI\alpha TL(L^2 + h^2)}{Ch^2 - 2BhL + GL^2} \quad [20]$$

$$F_y = \frac{EI\alpha Th(L^2 + h^2)}{Ch^2 - 2BhL + GL^2} \quad [21]$$

For symmetrical lines with hinged ends $h = 0$, $F_y = 0$, and

$$F_x = \frac{EI\alpha TL}{G} \quad [22]$$

For symmetrical lines with hinged ends the angular rotation of either end is

$$\phi_1 = -\frac{\alpha TLF}{2G} \quad [23]$$

F—Development of General Equations for Any One-Plane Pipe Line With Partially Fixed Ends

The fixity of either end of any pipe line may be defined as a function of the amount of rotation of that end by assuming that the fixity of a fully fixed end is unity and that the fixity of a hinged end is zero. As an aid in visualizing this effect and as an aid in the mathematical derivation, we shall also assume that the distance of the neutral axis from an end is proportional to the fixity of that end if the other end is hinged. In estimating the fixity of an end, then, we mentally compare the rotation of that end with the rotation of the same end if it were hinged and assign a corresponding value of the fixity. Thus, if we estimate that the end can rotate one-third as much as if it were free, we assign the end a fixity of two-thirds.

The neutral axis, line of thrust, or line of zero moment, for a symmetrical pipe line fully fixed at both ends, is a horizontal line through the center of gravity of the line. For a hinged-

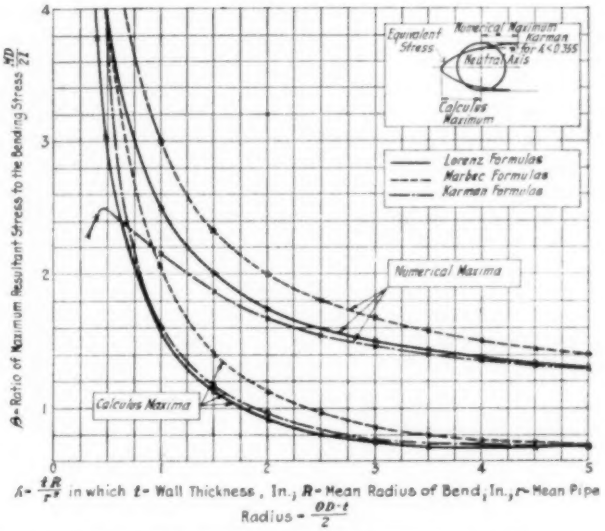

Fig. 7 Values of Equivalent Stress Constant β as Given by Various Investigators

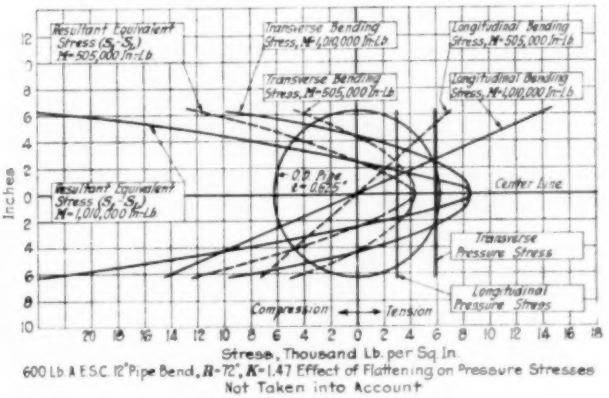

Fig. 8a Stress Distribution in Typical Pipe Bend

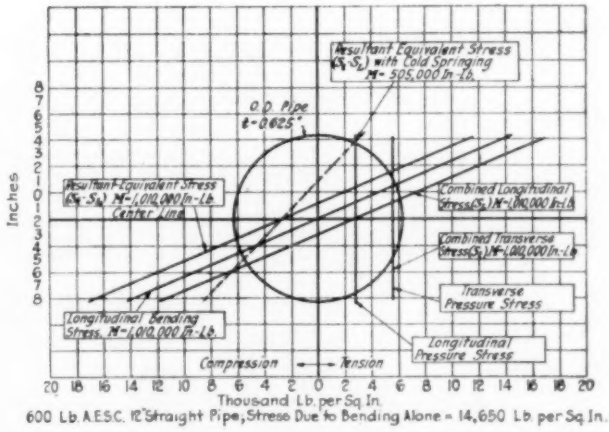

Fig. 8b Stress Distribution in Typical Straight Pipe

end pipe line it passes through the hinges. For intermediate cases with equal fixity at the ends the neutral axis will be between these two extremes. If one end is hinged and the other is in some degree fixed, the neutral axis will appear as in Fig. 1. The following theory is based on the assumption that the distance M_0/V of the neutral axis from the partly or wholly fixed end is proportional to the fixity of that end, the other end remaining hinged. If the partly or wholly fixed end remains unchanged as to fixity and the hinged end has its fixity increased from zero to some other value, the value of M_0/V for the originally fixed end will change, hence M_0/V is then a function of the fixities of both ends, whether they are equal or unequal.

Under the above assumption we have the equation pertaining to the left end of the bend $M_0/V = m_0(K_0 - K_1m_1)$ and that pertaining to the right end of the bend, $M_1/V = m_1(K_2 - K_3m_0)$

where M_0 = moment at left end
M_1 = moment at right end
m_0 = fixity at left end
m_1 = fixity at right end
V = resultant force on the bend $= \sqrt{(F_x^2 + F_y^2)}$

K_0, K_1, K_2, K_3 are constants depending on the form of the bend. The M/V term in each is the distance of the neutral axis from the end in question. Note that each distance is a function of the fixity at both ends.

By a treatment similar to that used in the development of the fundamental equations, we derive the formulas that follow.

Case I—General. Supports at different levels; non-symmetrical with respect to an axis perpendicular to line joining ends of pipe line, fixity at ends equal or unequal; or symmetrical with respect to an axis perpendicular to line joining ends of pipe line, fixity at ends unequal.

$$F_x = \frac{EI\alpha T(L^2 + h^2)(L\sqrt{L^2 + h^2 - \psi^2} - \psi h)}{W(hA - LF)(L^2 + h^2) + \sqrt{L^2 + h^2 - \psi^2}(h^2C - 2hLB + L^2G) + \psi(hLC + h^2B - L^2B - hLG)} \quad [24]$$

$$F_y = \frac{EI\alpha T(L^2 + h^2)(\psi L + h\sqrt{L^2 + h^2 - \psi^2})}{\text{Same Denominator}} \quad [25]$$

$$M_0 = \frac{EI\alpha T(L^2 + h^2)^2 W}{\text{Same Denominator}} \quad [26]$$

where

$$\psi = m_1(K_2 - K_3m_0) - m_0(K_0 - K_1m_1) \quad [27]$$

$$W = m_0(K_0 - K_1m_1) \quad [28]$$

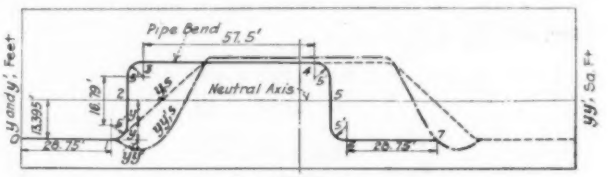

FIG. 9 GRAPHICAL SOLUTION OF A PIPE BEND

$$K_0 - K_1 = \frac{F(Bh + CL) - A(BL + Gh)}{\sqrt{[H(Bh + CL) - A(AL + Fh)]^2 + [H(BL + Gh) - F(AL + Fh)]^2}} \quad [29]$$

$$K_0 = \frac{h^2(B - LF - hA + hLH) + hL(C - 2AL + L^2H - G + 2hF - h^2H) - L^2(B - LF - hA + hLH)}{\sqrt{[h(B - LF - hA + hLH) + L(C - 2AL + L^2H)]^2 + [h(G - 2hF + h^2H) + L(B - LF - hA + hLH)]^2}} \quad [30]$$

$$K_2 - K_3 = \frac{(Bh + CL)(F - hH) + (BL + Gh)(HL - A) + (AL + Fh)(Ah - FL)}{\sqrt{[H(Bh + CL) - A(AL + Fh)]^2 + H[(BL + Gh) - F(AL + Fh)]^2}} \quad [31]$$

$$K_2 = \frac{L(Gh + BL) - h(Bh + CL)}{\sqrt{(Bh + CL)^2 + (Gh + BL)^2}} \quad [32]$$

If the bend is symmetrical with respect to an axis perpendicular to the line joining the ends of the bend, then

$K_0 = K_2$, $K_1 = K_3$, $\psi = K_0(m_1 - m_0)$, and $W = m_0(K_0 - K_1m_1)$

hence find K_0 from [32] and K_1 from [29].

Having found the constants needed, solve for ψ and W and obtain M_0, F_x, and F_y from Equations [24], [25], and [26].

Case II. Supports at different levels; symmetrical with respect to an axis, perpendicular to line joining ends of pipe line, fixity at ends equal. In this case $m_1 = m_0 = m$, hence $\psi = 0$. Then

$$F_x = \frac{EI\ \alpha\ TL(L^2 + h^2)}{W(hA - LF)\sqrt{L^2 + h^2} + h^2C - 2hLB + L^2G} \quad [33]$$

$$F_y = \frac{EI\alpha Th(L^2 + h^2)}{\text{Same Denominator}} \quad [34]$$

$$M_0 = \frac{EI\alpha TW(L^2 + h^2)^{3/2}}{\text{Same Denominator}} \quad [35]$$

$$K_0 = \frac{L(Gh + BL) - h(Bh + CL)}{\sqrt{(Bh + CL)^2 + (Gh + BL)^2}} \quad [36]$$

$$K_0 - K_1 = \frac{F(Bh + CL) - A(Gh + BL)}{\sqrt{[H(Bh + CL) - A(AL + Fh)]^2 + [H(Gh + BL) - F(AL + Fh)]^2}} \quad [37]$$

Case III. Supports at same level; non-symmetrical with respect to a vertical axis, fixity at ends equal or unequal; or symmetrical with respect to a vertical axis, fixity at ends unequal. This is the same as Case I with $h = 0$. Hence

$$F_x = \frac{EI\alpha TL\sqrt{L^2 - \psi^2}}{G\sqrt{L^2 - \psi^2} - WLF - B\psi} \quad [38]$$

$$F_y = \frac{EI\alpha TL\psi}{G\sqrt{L^2 - \psi^2} - WLF - B\psi} \quad [39]$$

$$M_0 = \frac{EI\alpha TL^2 W}{G\sqrt{L^2 - \psi^2} - WLF - B\psi} \quad [40]$$

$$K_0 - K_1 = \frac{CF - AB}{\sqrt{(CH - A^2)^2 + (BH - AF)^2}} \quad [41]$$

$$K_0 = \frac{L(LF - B)}{\sqrt{(C - 2AL + HL^2)^2 + (LF - B)^2}} \quad [42]$$

$$K_2 - K_3 = \frac{(CF - AB) + L(BH - AF)}{\sqrt{(CH - A^2)^2 + (BH - AF)^2}} \quad [43]$$

$$K_2 = \frac{BL}{\sqrt{B^2 + C^2}} \quad [44]$$

If the bend is symmetrical with respect to a vertical axis, then $K_0 = K_2$, $K_1 = K_3$, $\psi = K_0(m_1 - m_0)$, $W = m_0(K_0 - K_1 m_1)$, K_0 results from [44], and $K_0 - K_1 = F/H$.

Case IV. Supports at same level; symmetrical with respect to a vertical axis, fixity at ends equal. This is the same as Case II with $h = 0$.

Hence

$$F_x = \frac{EI\alpha TL}{G - WF} \quad [45]$$

$$F_y = 0$$

$$M_0 = \frac{EI\alpha TLW}{G - WF} \quad [46]$$

$$K_0 = \frac{BL}{\sqrt{B^2 + C^2}} \quad [47]$$

$$K_0 - K_1 = F/H \quad [48]$$

$$W = m(K_0 - K_1 m) \quad [49]$$

For symmetrical lines with equal fixities at the ends it may be assumed that the moment at the ends varies directly as the fixity (i.e., $M_0 \propto m$). This approximation is believed to be sufficiently close for practical purposes in the simpler shapes.

G—General Equations for Effect of Force or Moment Applied at Any Point of Any One-Plane Pipe Line With Fixed Ends

Equations [50] to [58] make possible the solution of pipe lines with branches, since the branch may be replaced by P, Q, and M_B. Simultaneous solution of the equations for the branch and the main line can be performed by noting that P, Q, and M_B are the same for the branch and the main line. The integrals A, B, C, F, G, and H are found from Table 1 by adding up the values of the integrals for each part of the entire pipe line. The integrals A_1, B_1, C_1, F_1, G_1, and H_1 are similarly found from Table 1 by adding up the integrals for the part of the pipe line between points p and 1, i.e., for the part of the pipe line to the right of the load.

H—Development of General Equations for Deflection of Any Point in Any One-Plane Pipe Line

Let P be a point with coordinates x_1, y_1 referred to O on a pipe line whose left end is at O, and A any point between P and O. The y projection of the deflection due to bending, of P relative to O is given by $+(1/EI)\int_P^O Mx'ds$ and the x projec-

(*a*) Due to Vertical Force, P

$$M_0 = \frac{P[(C_1 - x_pA_1)(BF - AG) + (B_1 - x_pF_1)(AB - CF) + (A_1 - x_pH_1)(CG - B^2)]}{2ABF + HGC - A^2G - B^2H - CF^2} \quad [50]$$

$$F_x = \frac{P[(C_1 - x_pA_1)(BH - AF) + (B_1 - x_pF_1)(A^2 - CH) + (A_1 - x_pH_1)(CF - AB)]}{\text{Same Denominator}} \quad [51]$$

$$F_y = \frac{P[(C_1 - x_pA_1)(GH - F^2) + (B_1 - x_pF_1)(AF - BH) + (A_1 - x_pH_1)(BF - AC)]}{\text{Same Denominator}} \quad [52]$$

(*b*) Due to Horizontal Force, Q

$$M_0 = \frac{Q[(B_1 - A_1y_p)(AG - BF) + (G_1 - F_1y_p)(CF - AB) + (F_1 - H_1y_p)(B^2 - CG)]}{\text{Same Denominator}} \quad [53]$$

$$F_x = \frac{Q[(B_1 - A_1y_p)(AF - BH) + (G_1 - F_1y_p)(CH - A^2) + (F_1 - H_1y_p)(AB - CF)]}{\text{Same Denominator}} \quad [54]$$

$$F_y = \frac{Q[(B_1 - A_1y_p)(F^2 - GH) + (G_1 - F_1y_p)(BH - AF) + (F_1 - H_1y_p)(AG - BF)]}{\text{Same Denominator}} \quad [55]$$

(*c*) Due to Moment, M_B

$$M_0 = \frac{M_p[A_1(BF - AG) + F_1(AB - CF) + H_1(CG - B^2)]}{\text{Same Denominator}} \quad [56]$$

$$F_x = \frac{M_p[A_1(BH - AF) + F_1(A^2 - CH) + H_1(CF - AB)]}{\text{Same Denominator}} \quad [57]$$

$$F_y = \frac{M_p[A_1(GH - F^2) + F_1(AF - BH) + H_1(BF - AG)]}{\text{Same Denominator}} \quad [58]$$

tion by $-(1/EI)\int_P^O My'ds$ where x' and y' are measured from P as origin. From Fig. 5, $x' = x_1 - x$ and $y' = y_1 - y$, where x and y are the coordinates of A referred to O as origin. We have by substitution in the above formulas,

$$dy_1 = (1/EI)\int_O^P M(x_1 - x)ds$$

and

$$dx_1 = -(1/EI)\int_O^P M(y_1 - y)ds$$ where dy_1 and dx_1 are the y and x displacements of P relative to O, and x and y are measured from O. Due to a rise in temperature T, a y deflection of amount $\alpha T y_1$ and an x deflection of amount $\alpha T x_1$ are also produced, so that our final expression for the y and x deflections of any point P relative to the left end become

$$dy_1 = \frac{1}{EI}\int_O^P M(x_1 - x)ds + \alpha T y_1 \quad \ldots\ldots [59]$$

$$dx_1 = -\frac{1}{EI}\int_O^P M(y_1 - y)ds + \alpha T x_1 \quad \ldots\ldots [60]$$

Case I—Unsymmetrical Line With Fixed Ends. In the notation of Part III *D*, Equations [59] and [60] become

$$dy_1 = \frac{1}{EI}[M_0(x_1H' - A') - F_x(x_1F' - B') + F_y(x_1A' - C)] + \alpha T_{y1} \quad \ldots\ldots [61]$$

$$dx_1 = -\frac{1}{EI}[M_0(y_1H' - F') - F_x(y_1F' - G') + F_y(y_1A' - B')] + \alpha T x_1 \quad \ldots\ldots [62]$$

Where A', B', C', etc. are the integrals from the left-hand end of the line up to the point P where the deflections are desired.

Case II—Symmetrical Line With Fixed Ends. In this case $F_y = 0$ and

$$dy_1 = \frac{1}{EI}[M_0(x_1H' - A') - F_x(x_1F' - B')] + \alpha T_{y1} \quad \ldots [63]$$

$$dx_1 = \frac{1}{EI}[M_0(y_1H' - F') - F_x(y_1F' - G')] + \alpha T_{x1} \quad \ldots [64]$$

In particular, the vertical deflection of the middle point of a symmetrical fixed-end pipe line is given by

$$dy_1 = \frac{\alpha TL}{GH - F^2}(B'H - A'F) + \alpha T_{y1} \quad \ldots\ldots [65]$$

Case III—Unsymmetrical Line With Hinged Ends. In this case $M_0 = 0$ and

$$dy_1 = \frac{1}{EI}[-F_x(x_1F' - B') + F_y(x_1A' - C')] + \alpha T_{y1} \quad \ldots [66]$$

$$dx_1 = -\frac{1}{EI}[-F_x(y_1F' - G') + F_y(y_1A' - B')] + \alpha T_{x1} \quad \ldots [67]$$

Note that for hinged ends these deflections are relative to the left end, that is, when plotted as offsets to the original curve they will give a figure similar to the dotted curve of Fig. 6. This dotted curve is the deformed line rotated so that the tangents at the left end coincide. In less technical language, the deflections given by Formulas [66] and [67] will give the correct shape of the deformed line but not in its correct position.

Case IV—Symmetrical Line With Hinged Ends. Here $F_y = 0$ and the formulas become

$$dy_1 = \frac{1}{EI}[-F_x(x_1F' - B')] + \alpha T_{y1} \quad \ldots\ldots [68]$$

$$dx_1 = -\frac{1}{EI}[-F_x(y_1F' - G')] + \alpha T_{x1} \quad \ldots\ldots [69]$$

As in Case III, these deflections correspond to the dotted curve of Fig. 6.

In particular, the actual vertical deflection of the middle point of a symmetrical hinged-end pipe line (above its original position) is given by

$$dy_1 = \frac{F_xB'}{EI} + \alpha T_{y1} = \alpha T\left(\frac{LB'}{G} + y_1\right) \quad \ldots\ldots [70]$$

Case V—Symmetrical or Unsymmetrical Line With Partially Fixed Ends. For a pipe line that is unsymmetrical or for which the fixity at the ends is different, use Equations [61] and [62] and for a symmetrical pipe line with equal fixity at the ends, use Equations [63] and [64]. In either case, the deflections will correspond to a curve of the form shown in Fig. 6.

J—Flexibility Constant, *K*

In the common bending theory no account is taken of the deformation of the cross-section of the beam. In the case of pipes with comparatively thin walls, consideration of this deformation becomes necessary, as such pipes prove much more flexible during bending than can be accounted for by the ordinary theory.

It has been shown by several investigators that a factor K which may be called the flexibility constant, introduced into the ordinary bending formulas, will allow for this added flexibility. See Part II for brief description of mathematical work and Fig. 13 for plot of equations. Test data by Hovgaard seems to indicate that the distribution of longitudinal stress is more nearly in accordance with the Karman than with the other theories. However, since the test data are so meager and since the Lorenz formula appears to be more reasonable from a mathematical standpoint, as shown by Table 2, we shall use the Lorenz formula in the remainder of this paper.

TABLE 2 COMPARISON OF THEORIES OF LORENZ, KARMAN, AND MARBEC

Basis of comparison	Lorenz	Karman	Marbec
When $\beta = 0$	K = infinity	$K = 10$	K = infinity
β curve	One curve over entire range	2 curves	One curve
Simplicity of formulas	1st choice	3rd choice	2nd choice
Apparent agreement with test data (see Fig. 13)	1st choice	2nd choice	3rd choice
Assumption forming basis of theory	Deformed cross-section doubly symmetrical, no assumption as to shape of curve	Mean circumference remains unchanged	Cross-section takes shape of ellipse

K—Stresses at Any Point in Any One-Plane Pipe Line

At any cross-section of a pipe line subject to a rise in temperature T and an internal pressure p, there are six more or less important stresses to be considered. These are:

1 A longitudinal stress S_l parallel to the axis of the pipe, due to bending. This stress varies from zero at the neutral axis of the cross-section to a maximum at, or near, the fibers farthest from the neutral axis.

2 A transverse stress S_t perpendicular to the axis of the pipe, due to bending, and produced by the tendency of the cross-section to flatten. This stress is computed on the assumption of linear distribution of the bending stress across the pipe wall.

(*Text continued on p. 425*)

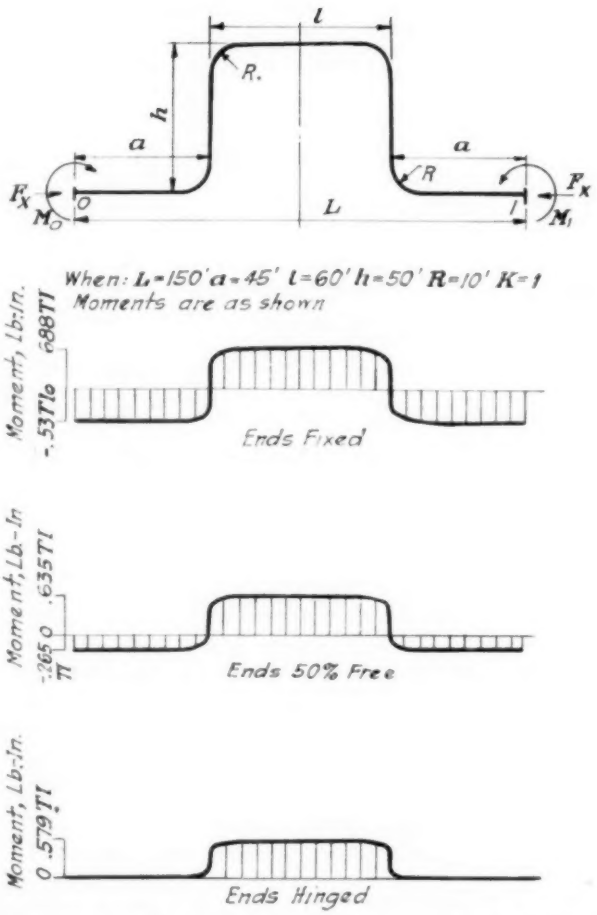

FIG. 10a MOMENT DIAGRAMS FOR VARIOUS END CONDITIONS, ONE-PLANE PIPE LINES

Formulas for Fig. 10a

$$F = h(h - 4R + l + \pi KR)$$

$$G = KR(1.42R^2 - 2.28hh + \pi h^2) + h\left(hl - 4hR + \frac{2h^2}{3} + 2R^2\right) - \frac{4R^3}{3}$$

$$H = 2\left(a + h + \frac{l}{2} - 4R + \pi KR\right)$$

Ends fixed:

$$M_o = M_1 = \frac{EI\alpha TLF}{GH - F^2}$$

$$F_x = \frac{EI\alpha TLH}{GH - F^2} \text{ and } F_y = 0$$

Ends partly free:

$$M_o = M_1 = \frac{EI\alpha TLF\,(1 - n)}{GH - F^2}$$

$$F_x = \frac{EI\,\alpha\,TLH\left(1 - \frac{nF^2}{GH}\right)}{GH - F^2} \text{ and } F_y = 0$$

where n = degree of freedom in the approximate formula.

Ends hinged:

$$M_o = M_1 = 0$$

$$F_x = \frac{EI\alpha TL}{G} \text{ and } F_y = 0$$

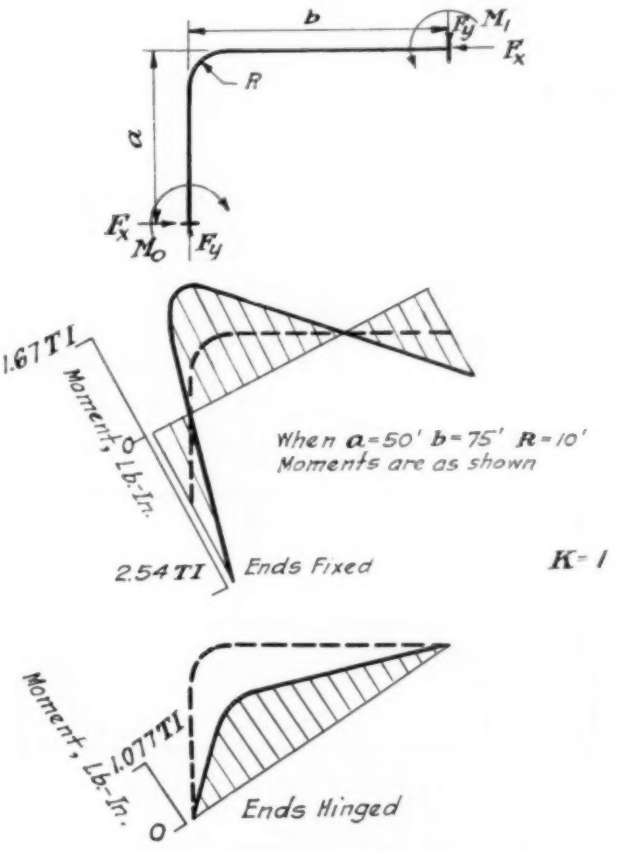

FIG. 10b MOMENT DIAGRAMS FOR VARIOUS END CONDITIONS, ONE-PLANE PIPE LINES

Formulas for Fig. 10b

$$A = 0.57KR^2 + \frac{b^2 - R^2}{2}$$

$$B = (0.57a - 0.07R)KR^2 + \frac{a(b^2 - R^2)}{2}$$

$$C = 0.355KR^3 + \frac{b^3 - R^3}{3}$$

$$F = (1.57a - 0.57R)KR + \frac{a^2 + 2a(b - 2R) + R^2}{2}$$

$$G = (1.57a^2 - 1.14aR + 0.355R^2)KR + \frac{a^3 - 6a^2R + 3a^2b + 3aR^2 - R^2}{3}$$

$$H = 1.57KR + a + b - 2R$$

Ends fixed:

$$M_0 = \frac{EI\alpha T[F(Ba + Cb) - A(Bb + Ga)]}{2ABF + CGH - A^2G - B^2H - CF^2}$$

$$F_x = \frac{EI\alpha T[H(Ba + Cb) - A(Ab + Fa)]}{2ABF + CGH - A^2G - B^2H - CF^2}$$

$$F_y = \frac{EI\alpha T[H(Bb + Ga) - F(Ab + Fa)]}{2ABF + CGH - A^2G - B^2H - CF^2}$$

$$M_1 = M_0 - F_x a + F_y b$$

Ends hinged:

$$M_0 = M_1 = 0$$

$$F_x = \frac{EI\alpha T(b^2 + a^2)b}{a^2c - 2Bba + Gb^2} \text{ and } F_y = \frac{EI\alpha T(b^2 + a^2)a}{a^2C - 2Bba + Gb^2}$$

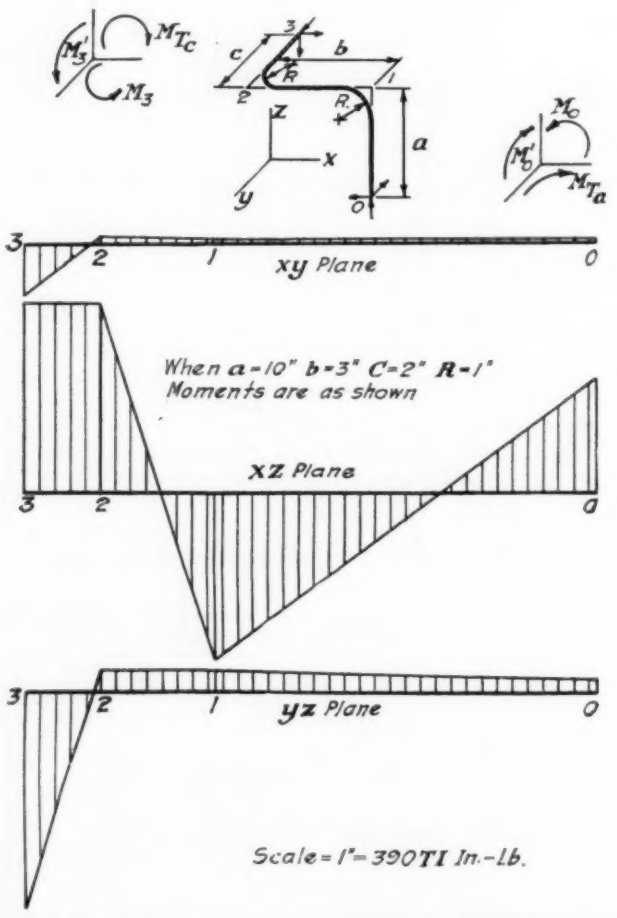

FIG. 10c MOMENT DIAGRAMS FOR TYPICAL PIPE LINE IN MORE THAN ONE PLANE

Formulas for Fig. 10c

$$B_1 = \frac{a^2 + R^2(1.14K - 1)}{2} = c + \frac{a^2 - c^2}{2}$$

$$C_1 = 2b + 2a + \frac{5}{2}(C - R)$$

$$F_1 = \frac{cN(c + H)}{H + 2c}$$

$$G_1 = \frac{a^3 + c^3 + R^3(3.42K - 3)(a + c) - R^3(4.26K - 4)}{6}$$

$$H_1 = 0.071KR^3 - \frac{c^2G}{H + 2c}$$

$$A_2 = \frac{1}{A_1}\left[0.07KR^3 - \frac{bN(H - b)}{H + 2c}\right]$$

$$B_2 = 0.07KR^3 - \frac{a^2A}{C_1}$$

$$C_2 = \frac{B_1(b^2 + 2ab - bC_1) + 0.07KR^3C_1}{A(b^2 + 2ab) - BC_1}$$

$$F_2 = \frac{A}{C_1}(b^2 + 2ab) - B$$

$$G_2 = \frac{(b - cA_2 - aC_2)}{aB_1\left(1 - \frac{a}{c_1}\right) + F_1 - G_1 - A_2H_1 - B_2C_2}$$

(*Continued from p. 422*)

It is a maximum at either $y = o$ or $y = r$. At $y = o$, it is compressive on the inside of the wall and tensile on the outside of the wall. The reverse is true at $y = r$.

3 A transverse compression S_{tc} due to the resultant forces on the top and bottom halves of the bend. This compressive stress is a maximum at the neutral axis of the cross-section and decreases to zero at the top and bottom of the pipe.

4 A transverse tension S_{tp} due to the internal pressure. This tensile stress is constant over the entire cross-section under the assumption of a thin cylinder.

5 A longitudinal tension S_{lp} due to the internal pressure. This tensile stress is also constant over the entire cross-section.

6 A longitudinal compression S_{ln} due to the direct thrust N in the pipe. This compressive stress is constant over the entire cross-section and is ordinarily small.

Of these stresses, 1, 2, and 3 are variable over the cross-section while 4, 5, and 6 are considered constant over the cross-section. Formulas for 1, 2, and 3 will depend upon the assumptions used by the investigator and consequently there are three sets of formulas corresponding to the work of Karman, Marbec, and Lorenz.

Formulas for Brittle Materials, Such as Cast Iron. The maximum principal stress may be either tensile or compressive. Ordinarily, stresses 4, 5, and 6 are not taken into account, and it is then necessary to compute only max. S_l (tensile or compressive), and max. S_t + max. S_{tc} (compressive) and compare

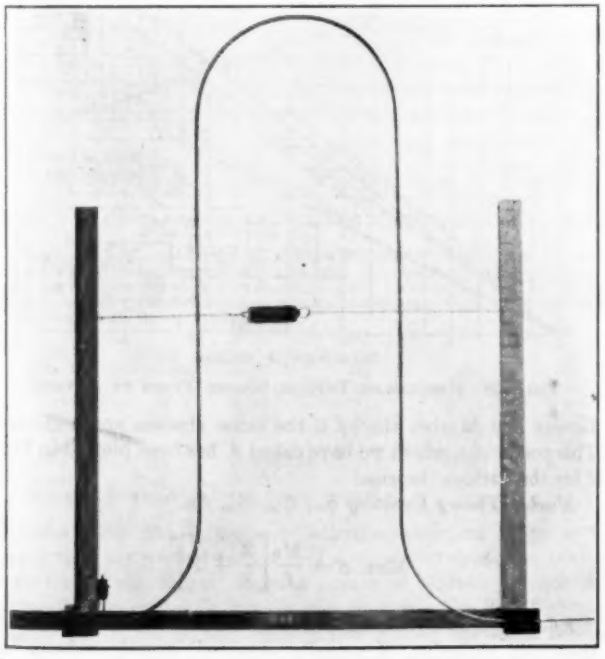

Fig. 11*b*

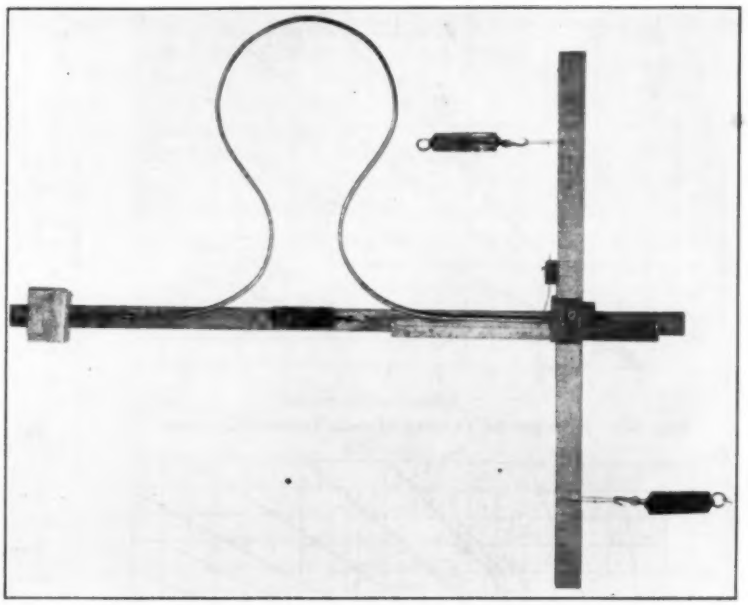

Fig. 11*a* Typical Model Test Set-Ups Employed

these values, using the greater. In this case, using the formulas of Karman with values of S_{tc} by Hovgaard;

$$\text{max. } S_l = \frac{Mr}{I}\frac{4}{9\sqrt{2}}\left[\frac{(5 + 6\lambda^2)^{3/2}}{1 + 12\lambda^2}\right] \quad [71]$$

$$\text{max. } S_t + \text{max. } S_{tc} = \frac{Mr}{I}\frac{2}{R}\left[\frac{9\lambda R + r + 6\pi\lambda^2}{1 + 12\lambda^2}\right] \quad [72]$$

For the same case using the formulas of Lorenz:

$$\text{max. } S_l = \frac{Mr}{I} \quad [73]$$

$$\text{max. } S_t + \text{max. } S_{tc} = \frac{Mr}{I}\left[\frac{3}{2\lambda} + \frac{r}{R}\right] \quad [74]$$

Formulas for Ductile Materials, Such as Steel, Lorenz Theory. If we omit the relatively small stress S_{tc} and the stresses S_{tp}, S_{lp}, S_{ln}, and restrict values of λ to those <6, we have the maximum equivalent stress in the pipe always equal to

$$\frac{Mr}{I}\left[\frac{3}{2\lambda} + 1\right] \quad [75]$$

Karman Theory, Omitting S_{tc}, S_{tp}, S_{lp}, S_{ln}. This case has been developed by Wahl and the formulas are:

$$S_1 = \frac{Mr}{I}\left[\frac{8\lambda - 36\lambda^3 - \left(32\lambda^2 + \frac{20}{3}\right)\sqrt{\frac{4}{3}\lambda^2 + \frac{5}{18}}}{1 + 12\lambda^2}\right] \quad [76]$$

$$S_2 = \frac{Mr}{I}\left[\frac{8\lambda - 36\lambda^3 + \left(32\lambda^2 + \frac{20}{3}\right)\sqrt{\frac{4}{3}\lambda^2 + \frac{5}{18}}}{1 + 12\lambda^2}\right] \quad [77]$$

$$S_3 = \frac{Mr}{I}\left[\frac{-12\lambda^2 - 18\lambda + 2}{1 + 12\lambda^2}\right] \quad [78]$$

with the rule

For $0.3 < \lambda < 0.335$, use S_1 or S_2

For $\lambda > 0.335$, use S_2 or S_3

TABLE 3 COMPARISON OF THEORY WITH TESTS OF FIGS. 12c AND 12e

Δx, in.	F_x (observed), lb.	F_x (computed), lb.
Equal fixities, 8-in. arm at each end		
7/16	0.5	0.55
27/32	1.00	1.07
1 1/16	1.25	1.35
Unequal fixities, arm 8-in. at left, 4-in. at right		
17/32	0.5	0.55
25/32	0.75	0.81
1 1/16	1.00	1.09

It is obvious that the coefficient of Mr/I in the foregoing equations can be plotted as a function of λ and values of this coefficient taken from the curve so obtained. This is equally true for the Lorenz and Marbec theory if the same stresses are neglected. This coefficient, which we have called β, has been plotted in Fig. 7 for the various theories.

Marbec Theory Omitting S_{1c}, S_{1p}, S_{1p}, S_{1s}.

$$\text{Max. } S = \frac{Mr}{I}\left[\frac{2}{\lambda} + 1\right] \qquad [79]$$

Effect of Cold Springing of Pipe. The curves of Fig. 8 show that cold springing (if actually obtained) greatly reduces the stresses in pipes.

Effect of Steam Pressure on Amount of Flattening. It has been shown by Wahl that this effect is negligible.

Summary. Adopting the Lorenz theory (see Part III, J) we have the equation for maximum stress in a pipe bend of a ductile material in the case where $\lambda < 6$, and where S_{tc} is omitted:

$$S = \frac{Mr}{I}\left[\frac{3}{2\lambda} + 1\right] + S_{tp} - S_{ip} + S_{in} \ldots\ldots [80]$$

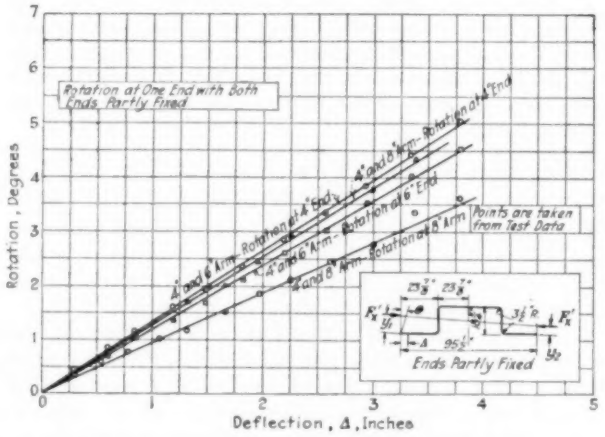

FIG. 12*g* RESULTS OF TYPICAL MODEL TESTS BY AUTHOR

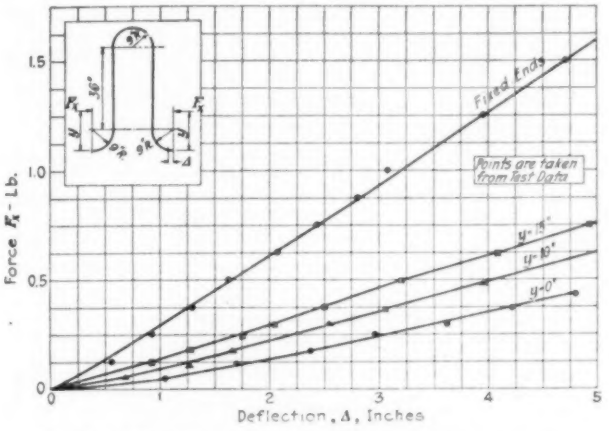

FIG. 12*h* RESULTS OF TYPICAL MODEL TESTS BY AUTHOR

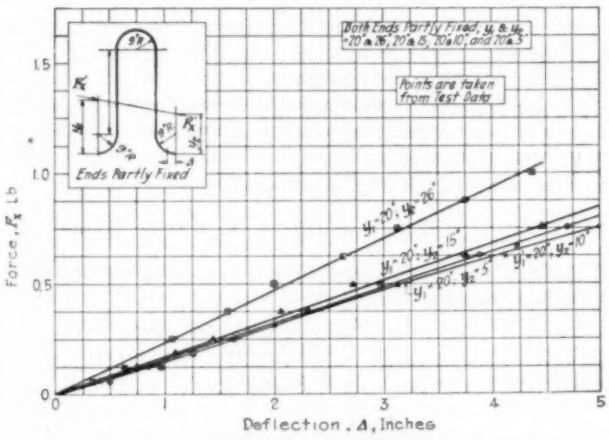

FIG. 12*j* RESULTS OF TYPICAL MODEL TESTS BY AUTHOR

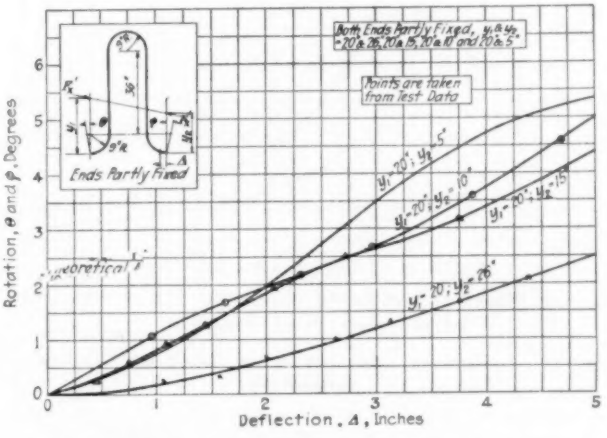

FIG. 12*k* RESULTS OF TYPICAL MODEL TESTS BY AUTHOR

TABLE 4 COMPARISON OF THEORY WITH TESTS OF FIGS. 12*h* AND 12*j*

Test data are consistently lower than the computed data, due probably to the distortion of the model. However, this difference is usually small, and the test results in the main show good agreement with the theory. The quantities m_0 and m_1 are the computed fixities at the left- and right-hand ends, respectively.

Left arm, in.	Right arm, in.	F_x computed, lb.	F_x observed, lb.	m_0	m_1
20	26	0.252	0.229	0.74	0.96
20	15	0.185	0.172	0.73	0.55
20	10	0.168	0.160	0.73	0.37
20	5	0.155	0.150	0.73	0.18
15	15	0.163	0.150	0.55	0.55
10	10	0.135	0.124	0.37	0.37
Free	Free	0.099	0.086	0	0
Fixed	Fixed	0.333	0.322	1	1

Referring to Fig. 7, an actual calculus maximum (slope = 0) exists near the neutral surface and a numerical maximum occurs near the outside fibers. For the Lorenz or Marbec theories the numerical maximum is always the greater. For the Karman theory the curve of equivalent stress follows the form shown dotted in the figure, and it becomes necessary to compare the calculus and numerical maxima in order to determine the greater. Both calculus and numerical maxima equal unity for all theories when λ equals infinity (i.e., for a straight pipe).

Study of Stress Distribution. Fig. 8*a* illustrates the stress distribution in a curved pipe under the more exact theory and indicates that it is much more complicated than has been generally realized. The longitudinal stress due to bending is added to the longitudinal stress due to pressure giving the curve of combined longitudinal stress. In a similar manner the transverse stress due to bending is added to the transverse stress due to pressure, giving the curve of combined transverse stress. The resultant combined (equivalent) stress ($S_t - S_l$) is then obtained according to the maximum shear theory of failure, for ductile material.

Fig. 8*a* also shows the stresses due to bending when reduced one-half by cold springing. The pressure stresses are, of course, not changed by this means.

The same stresses are shown for a straight pipe in Fig. 8*b*. In this case the distribution is the same as in a beam, there being no flattening effect. This flattening effect would be much greater for piping with thinner walls than for the 600-lb. piping used in the illustration.

It is common practice to stress piping up to or beyond the elastic (or creep) limit as is witnessed by the common experience that some joints in a new installation will leak until the piping has set. This practice has proved satisfactory since that particular portion of the metal which is overstressed, yields (or creeps), thus relieving the moment on the line.

L—Study of Errors Due to Assumptions in Derivation

For the model pipe lines of Fig. 12, and others not published the magnitude of the errors involved in the assumptions of the derivation in Part III have been computed to illustrate concretely their importance.

a Direct compression. Error less than 0.1 per cent.

b Direct shear. Error less than 0.1 per cent.

c Effect of deflection on moment. In most cases the error was less than 5.0 per cent. In some long tangent free-end tests the error was cumulative with increasing force and reached as great a value as 20 per cent. However, the latter cases are not approached in practice and the error in practice is believed to be less than 5.0 per cent. This error is in the opposite direction to the other errors and will, in general, balance them so that the resultant error in practical installations can be considered small and on the safe side.

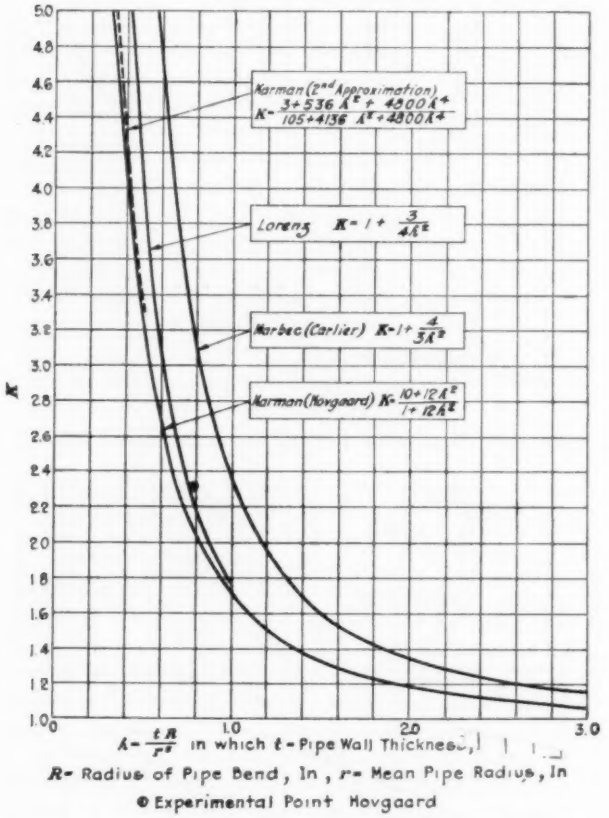

Fig. 13 Flexibility Constant K as Given by Various Investigators

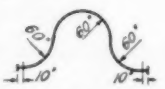
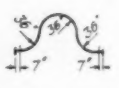
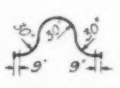
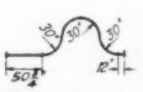
d Location of neutral axis of cross-section of pipe. The neutral axis of a straight bar subjected to bending passes through the center of area of the cross-section. For a curved bar, however, this is no longer strictly true, but it may be shown that the error due to this cause is usually only a fraction of one per cent for pipe bends.

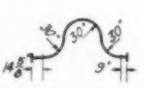
M—Graphical Method for Any One-Plane Pipe Line With Any End Conditions











Hovgaard (Reference *J*) gives illustrations of graphical solutions for several hinged-end bends. An illustration is here given, for a symmetrical fixed-end pipe line, of a method which will suggest solutions for any one-plane pipe line.

Referring to Fig. 9, the neutral axis of the pipe line will first be determined. In general, the distance n of the neutral axis from the line 0–7 through the ends is $n = (K\int yds)/(K\int ds)$. In other words, the neutral axis passes through the center of gravity of the pipe line if the ends are fixed and if K for all parts can be assumed to be the same. Assuming $K = 1$, from symmetry of the pipe line the neutral axis bisects each of the lengths b; therefore $n = b/2$. Replotting the pipe line against s instead of x, the (y, s) curve is obtained. As shown on the figure, at any distance s from the left-hand end, the distances y and y' can be read directly. Multiplying these two distances together at each point a curve is plotted whose ordinates are proportional to yy' and hence to $F_x yy'$ or M_y. The area under this curve for the entire pipe line is $\int Myds$, and from Equation [6]

$$\int Myds = EI\alpha TL = F_x \int yy'ds \quad \ldots\ldots\ldots [81]$$

Thus the desired relationship between F_x and αTL is obtainable from the area under the yy' curve, and

$$F_x = -\frac{EI\alpha TL}{\int yy'ds} \quad \ldots\ldots\ldots [82]$$

Fig. 14 Comparison of the Author's Theory With Previously Published Test Results

$$M_0 = F_x n \quad \ldots\ldots\ldots\ldots\ldots\ldots [83]$$

In Fig. 9 with $s = 40$ ft., $y = 7.6$ ft., $y' = 5.8$ ft., $yy' = -44.1$ For the entire line $\int yy'ds = 25{,}700$ cu. ft. Hence $F_x = -(EI\alpha TL)/25700$ and $M_0 = (EI\alpha TL)/1920$. These numerical values would, however, be appreciably different if $K = 2$, as it does in the curved portion of certain standard pipe bends. The correct value of K can, however, be included in plotting the yy' curve by multiplying the values by K wherever they occur. If the resulting discontinuities in the yy' curve are smoothed out by eye, the result probably corresponds closely to the experimentally observed values, since a discontinuity of K where a straight part joins a curved part is a practical impossibility.

The graphical method for an unsymmetrical line consists either of trial to get a minimum area in the moment diagram or of a combination of the graphical method with the equations of Table 1.

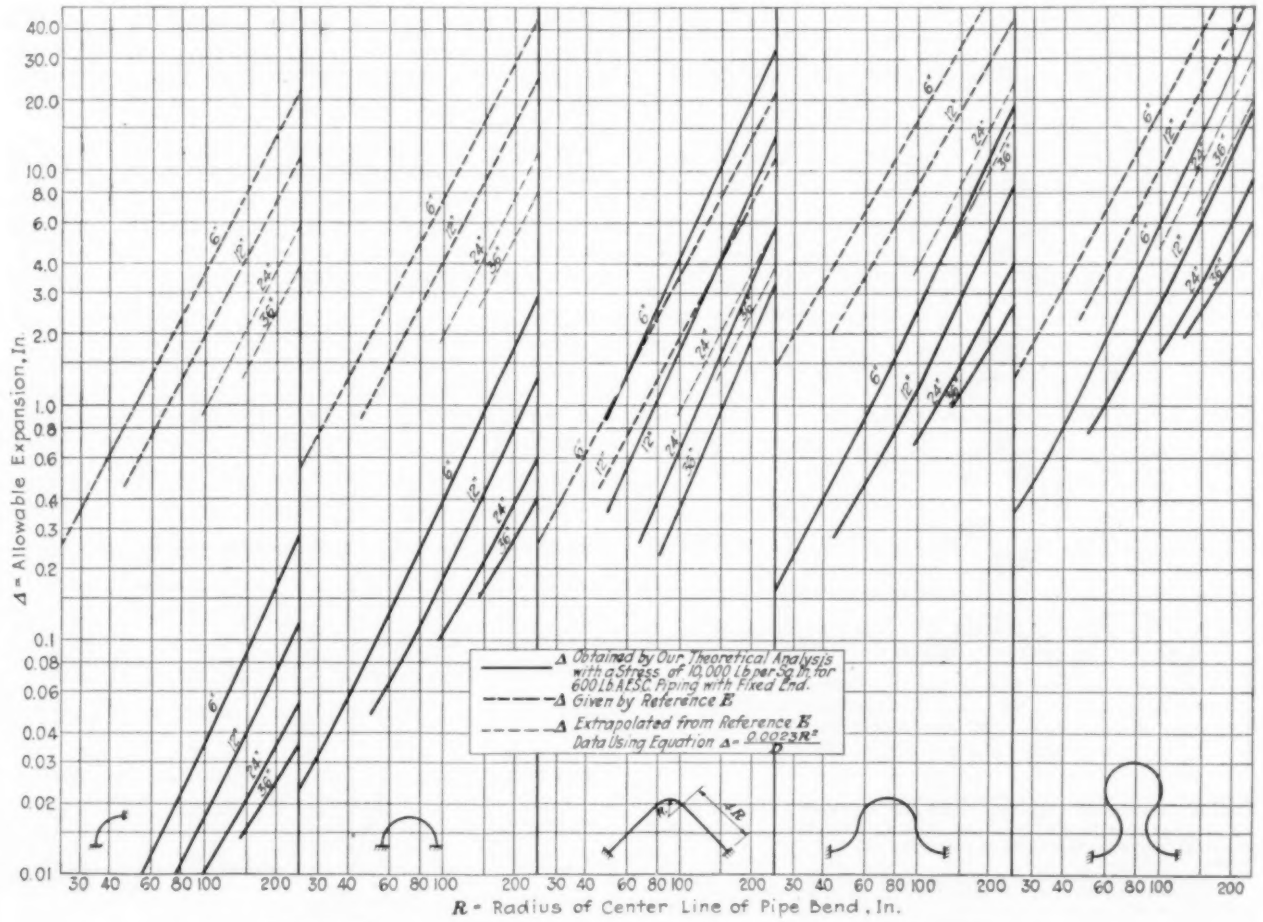
The graphical method for a pipe line with partially fixed ends consists of the application of the theory presented in Part III, F.

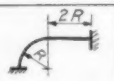
N—Analysis of Pipe Lines in More Than One Plane

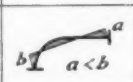
The exact analysis of pipe lines in more than one plane requires a very large amount of labor. There are in general twelve unknown quantities; three moments and three reactions at each end. Six equations are afforded by statics, leaving six more to be determined from consideration of the elastic deformation of the structure. On each branch of a multiplane pipe line there will be two bending moments in planes at right angles, and a torsional moment, hence the stress is produced by combined bending and torsion. The resulting bending moment on each section is equal to the square root of the sum of the squares of the two bending moments. This combined with the torsional moment by the ordinary formula for combined bending and torsion gives the stress in that section.

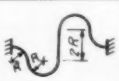
A general method for pipe lines in space has been developed, but has not been reduced to practical simplicity at this time.

In Fig. 10c the bending and torsional moments in a typical multiplane pipe line have been obtained and plotted. For the proportions chosen in the numerical example, the maximum resultant bending moment occurs at the right-hand end.









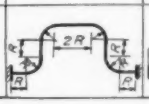


Fig. 15 Comparison Between Current Practice and Proposed Formulas

P—Moments and Reactions in Geometrically Similar Pipe Lines

Designate the ratio of each dimension (excepting those of the cross-section) on a given pipe line [1] to the corresponding dimension on a smaller but geometrically similar pipe line [2] by N. In the integrals in Equations [7], [8], and [9], every value of x, y, and s, and the ratio M_0/F_x for pipe line [1] is N times the corresponding value in pipe line [2]. With a given deflection,

$$\frac{F_{y1}}{F_{y2}} = \frac{F_{x1}}{F_{x2}} = \frac{1}{N^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [84]$$

and

No	Shape	Moment Diagram	M_o = Moment at Left End	F_x
I			$\frac{\mu_1 \Delta I}{K}$	$\frac{\mu_2 \Delta I}{K}$
II			$\mu_1 \Delta I \eta$	$\mu_2 \Delta I \eta$
III			$\mu_1 \Delta I \eta$	$\mu_2 \Delta I \eta$
IV			$\frac{0.095 \mu_1 \Delta I}{K}$	$\frac{0.04 \mu_2 \Delta I}{K}$
V			$\frac{0.006 \mu_1 \Delta I}{K}$	$\frac{0.00098 \mu_2 \Delta I}{K}$
VI			$\frac{0.0142 \mu_1 \Delta I}{K}$	$\frac{0.0039 \mu_2 \Delta I}{K}$
VII			$\mu_1 \Delta I \eta$	$\mu_2 \Delta I \eta$
VIII			$\mu_1 \Delta I \eta$	$\mu_2 \Delta I \eta$
IX			$\mu_1 \Delta I \eta$	$\mu_2 \Delta I \eta$
X			$\mu_1 \Delta I \eta$	$\mu_2 \Delta I \eta$

Note:- To Determine Maximum Moment Draw Moment Diagram. Moment Arm = $\frac{M_o}{F_x}$ for Symmetrical Bends
Then S Max. = M Max. $\frac{r\beta}{I}$

FIG. 16 FORMULAS FOR REACTIONS FOR COMMON TYPES OF BENDS

I = moment of inertia, Δ = deflection (or expansion) to be absorbed, and μ_1, μ_2, and η are constants given by Fig. 17.

NOTES:
1 Moment diagrams are not to a comparative scale.
2 Check both curved and straight portions for maximum stress.
3 Values of η for partial fixedness, while given for Case VIII only, may be worked out for other cases, if desired.
4 Curves of I or of $(r\beta)/I$ could be prepared for A.E.S.C. pipe.
5 E assumed to be 29×10^6.

$$\frac{M_{01}}{M_{02}} = \frac{1}{N^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [85]$$

For comparing two full-size pipe lines, however, it is more convenient to consider a given temperature change rather than a given deflection, and

$$\frac{F_{y1}}{F_{y2}} = \frac{F_{x1}}{F_{x2}} = \frac{1}{N^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [86]$$

and

$$\frac{M_{01}}{M_{02}} = \frac{1}{N} \quad \ldots\ldots\ldots\ldots\ldots\ldots [87]$$

The behavior of full-size pipe lines can be readily pre-determined from the behavior of models by means of these equations. They also indicate the factor by which to multiply the dimensions of an unsatisfactory layout to obtain without trial a satisfactory layout.

R—STUDY IN APPLICATION OF RESULTS OF THEORETICAL ANALYSIS TO TYPICAL PIPE LINES

Figs. 10*a* and 10*b* give equations resulting from Table 1 and moment diagrams for two typical one-plane pipe lines. Fig. 10*c* gives equations and moment diagrams for a typical multiplane line. The moment diagrams may be obtained graphically as is shown under Part III M or they may be computed algebraically from the equations accompanying Figs. 10*a*, 10*b*, and 10*c*.

On the moment diagrams, the line bounding the moments is not the pipe line although in some cases it is of similar proportions and shape. In each moment diagram the perpendicular distances from the neutral axis to the limiting line are the moments on the pipe.

Familiarity with these diagrams will suggest the drawing of others by inspection for other cases and will be found very helpful in design. It should be noted that the outer fiber toward the neutral axis is always in compression and that the outer fiber away from the neutral axis is always in tension. For the multiplane line it should be noted that if rotation of flanges on gaskets

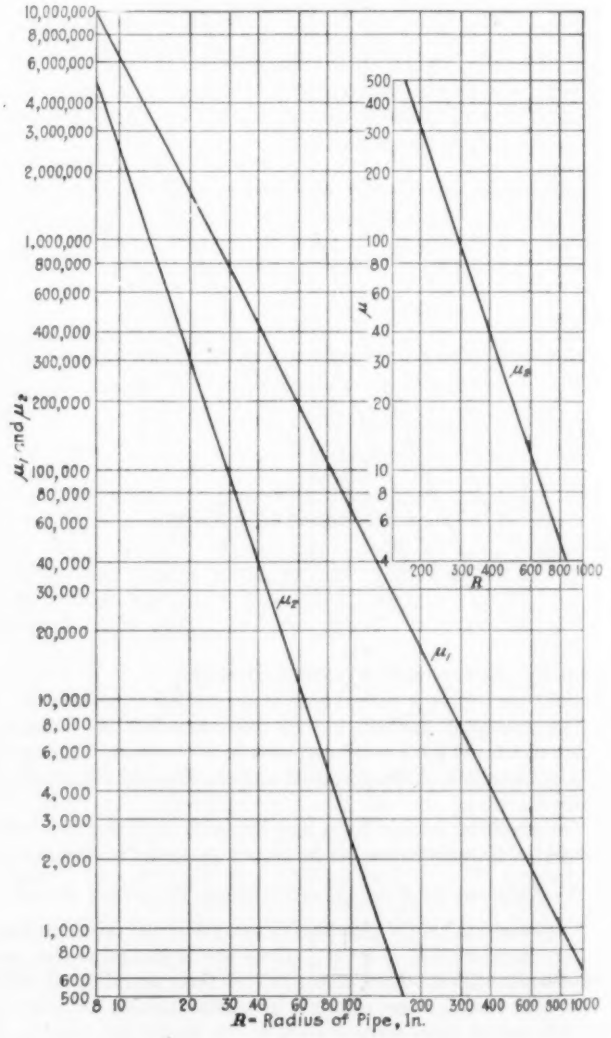

FIG. 17*a* VALUES OF CONSTANT μ

is allowable and is obtained in practice, the expansion stresses are greatly reduced since a rotation of 10 minutes makes a deflection of $^3/_8$ in. at a 10-foot radius and this may equal the total expansion to be absorbed.

PART IV—COMPARISON OF THEORY WITH EXPERIMENT AND WITH CURRENT PRACTICE

A—Load-Deflection Tests by Author on Solid Models

These tests were made on $^5/_{16}$-in. solid, cold-drawn bars and thus eliminate the variable flexibility constant K. See Fig. 11 for photograph of typical set ups, and Fig. 12 for plot of typical tests.

The actual diameter of the rod averaged 0.311 in. and this value was used in the computed curves. Tests of the material showed an average value of E of 29,000,000 lb. per sq. in.

Figs. 12*a* and 12*b* compare computed and observed values of reactions for a lyre-shaped model with and without tangents. It is seen that results are in close agreement for small values of

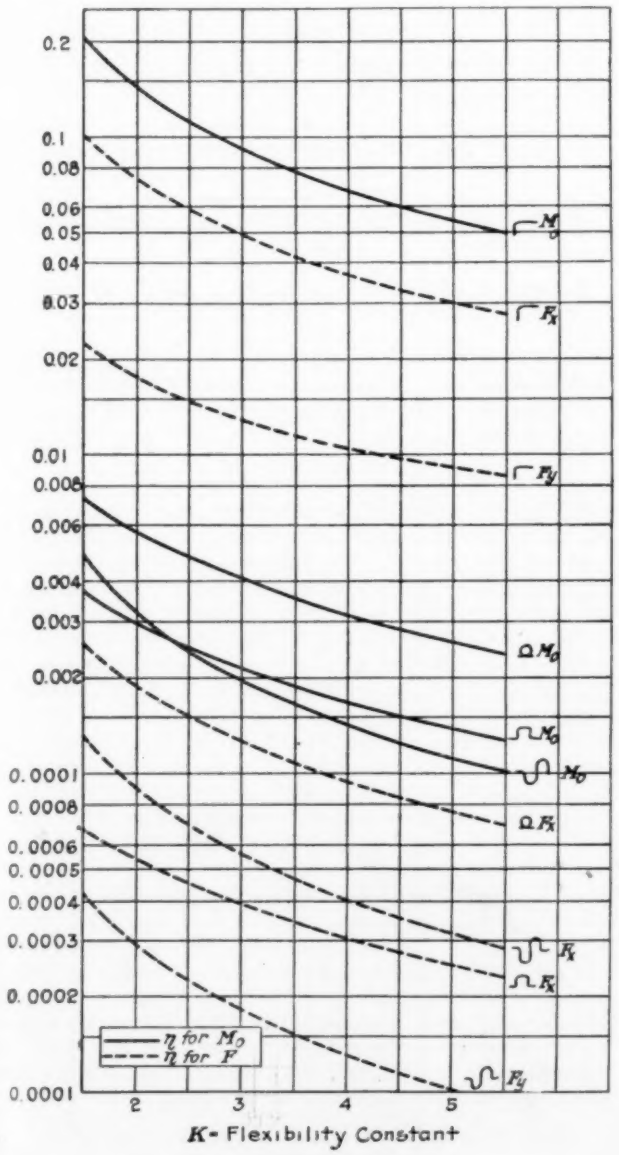

Fig. 17*b* Values of Constant η

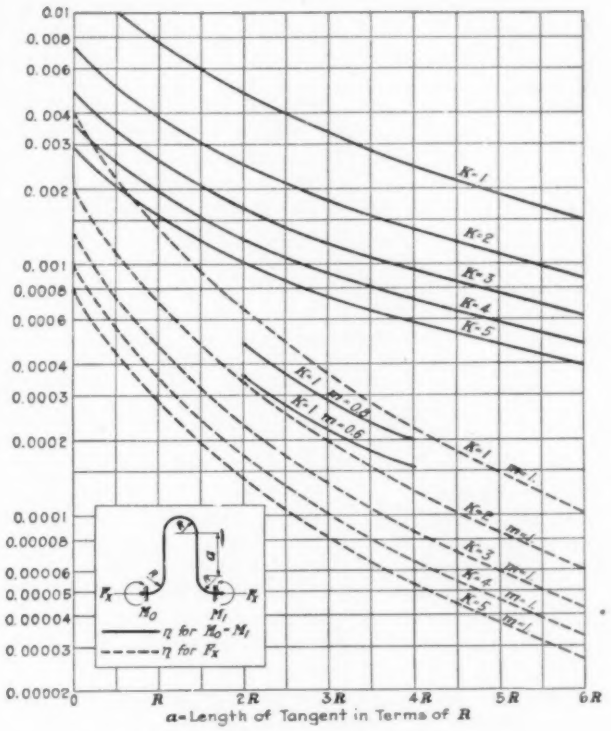

Fig. 17*c* Values of η for Hairpin Bends

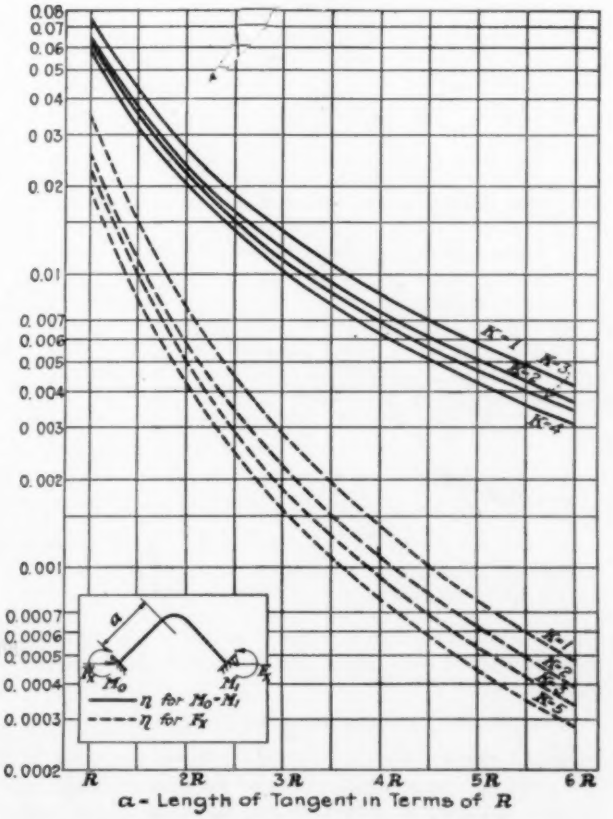

Fig. 17*d* Values of η for Quarter Bends With Tangents

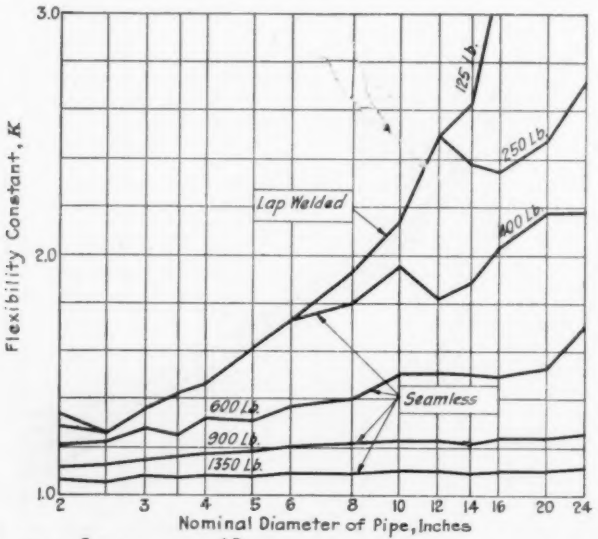
deflection. For larger values of deflection theory and experiment are still in close accord with fixed ends, but with hinged ends the flexibility is greater than indicated by theory, especially for long tangents. However, the larger values of deflection are greater relative to the length of the pipe line than would be obtained in practice, so that within practical limits the results check closely. These larger values of deflection produce a distorted shape so different from the original that close agreement between theory and test cannot be expected. In practice, ends are more nearly fixed than hinged, which also is on the side of accuracy.



Figs. 12, *c* to *j*, show the results of experiments to determine the effect of partially fixed ends. Values of force computed by the theory of fixity previously presented lie on lines drawn tangent to the experimental curves at the origin, again showing that for practical values of Δ the theory closely agrees with experiment.

Figs. 11*a* and *b* show photographs of two of the model pipe lines.

Sixty-four-ounce spring balances were used in measuring force and moment and a steel scale in measuring deflection. Specimens were suspended by long strings, thus eliminating friction. Spring scales were re-calibrated constantly and readings taken with both increasing and decreasing loads.

One end of the model shown in Fig. 11*a* was fixed by keeping the moment arm parallel to a series of pencil lines drawn on the sheet of paper under the apparatus, and the other was held in a wooden block with a steel bushing or in a vise.

Forces applied, as in the hairpin bend-test set-up, at any distance from the ends of the pipe determine the neutral axis. The moment at any point in the pipe equals the force applied

$K = 1 + \frac{3}{4\lambda^2}$; in which $\lambda = \frac{tR}{r^2}$; t = Pipe Wall Thickness; In.; r = Mean Pipe Radius = $\frac{OD - t}{2}$; $R = 6D$

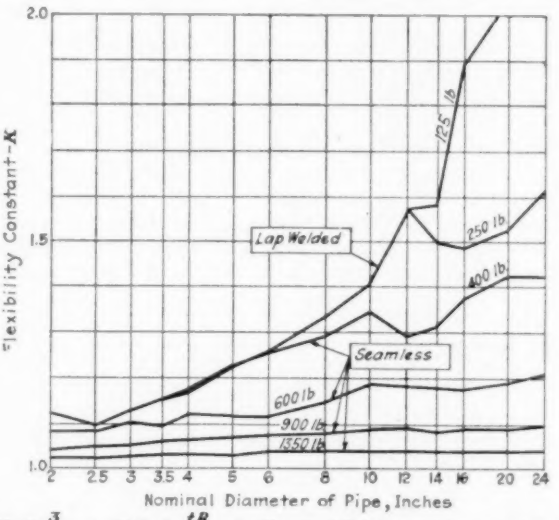


FIG. 18*a* VALUES OF FLEXIBILITY CONSTANT K FOR A.S.A. STANDARD PIPE WITH $R = 6D$

times the distance from the line of action of the force to the point (measured perpendicular to the line of action, or neutral axis).

B—PREVIOUSLY REPORTED TESTS

Fig. 13 shows the scarcity of test data on the value of K. The point by Hovgaard is considered the best published. The Crocker and Sanford data were not plotted since the ends of specimens were apparently partially fixed (see Fig. 14). The Wahl data were not plotted because of uncertainty as to end conditions of curved portions and the Bantlin data were not plotted because each specimen had two different radii.

Fig. 14 shows that the theory presented under Part III accounts for the apparent inconsistencies between previously reported tests. The free-end tests of Bantlin and Hovgaard show good agreement and the Crocker and Sanford tests are shown

$K = 1 + \frac{3}{4\lambda^2}$ in which $\lambda = \frac{tR}{r^2}$; t = Pipe Wall Thickness, In., r = Mean Pipe Radius = $\frac{O.D. - t}{2}$; $R = 10D$

FIG. 18*b* VALUES OF FLEXIBILITY CONSTANT K FOR A.S.A. STANDARD PIPE WITH $R = 10D$

to have partially fixed ends as would be expected from the method of making the tests. The assumption was made in computing Fig. 14 that both ends of all specimens were of equal degree of fixity.

C—CURRENT PRACTICE

Fig. 15 is a comparative study of the data used in current practice with that proposed as a result of the rational theory presented in Part III. The allowable deflections heretofore used are empirical and incomplete in that they give the same values for 125-lb. to 600-lb. piping and do not consider the influence of straight parts of the pipe lines. According to current practice a semicircle should have twice the allowable deflection of a quadrant of the same radius while the addition of straight portions of pipe would have no effect. Rational theory shows that this may give misleading results, as shown graphically by the first three bends here compared. A change from a quadrant to a semicircular bend actually multiplies the allowable deflection by about ten and the addition of straight portions with length equal to four times the radius of the bend, multiplies the quarter-bend values by about 100. That is, when a quadrant or semicircle is designed so that both ends are approximately fixed current practice would give unsatisfactory results, but when accompanied by sufficient additional flexibility in adjacent straight portions the data is satisfactory. It would be possible to make the results coincide by adding the proper length of straight pipe in each case, and this sometimes occurs in practice. Partial fixedness of the ends or thinner walls than used in the comparison or a combination of these two conditions would also in general bring them in closer agreement.

PART V—PROPOSED CODE OF DESIGN PRACTICE

To be of practical value rational formulas which take account

of all conditions must be derived and must be converted into workable formulas, tables, or graphs that the average engineer and draftsman can use. The following data are proposed as a preliminary code of practice. The importance of such a code is witnessed by the fact that the designer of most structures and machines can add metal and keep on the safe side when in doubt, whereas added metal in steam piping means added stiffness, and at least partial defeat of the object of safety in mind.

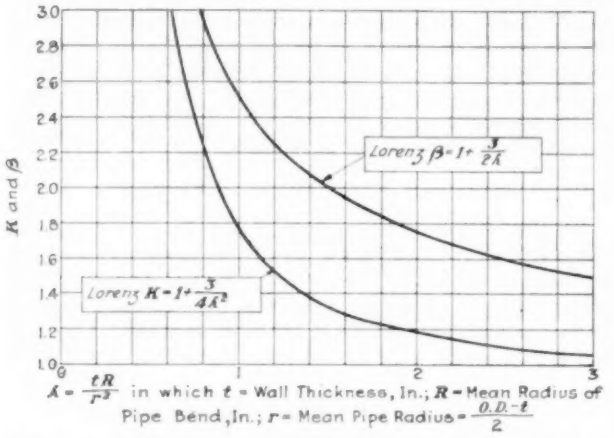

FIG. 19 VALUES OF FLEXIBILITY CONSTANT K AND EQUIVALENT STRESS CONSTANT β

A—PROCEDURE IN DESIGN

1 Make preliminary layout, from practical considerations, of the entire pipe line; and with principles of Part I in mind, locate anchors.

2 Decide on shape for best practical efficiency, by inspection, or study similar to Fig. 22, keeping joints away from points of high moment. Familiarity with the moment diagrams will be found of great help in performing much of the design by inspection.

3 Check the layout for reactions, stresses, and moments at joints, by means of the data given in Fig. 16 and Table 1. Consider, as far as practical, the entire section of the line between the anchors. Decide upon the amount of cold springing, the maximum being one-half of the total expansion. As noted under Part I, cold springing must be relied upon with caution to reduce stresses and reactions.

4 Design and place supports to allow the pipe line to move freely. This can be done most intelligently after computing or estimating the shape after deflection.

B—SUPPORTS AND ANCHORS

a Supports. Supports should be designed and placed to interfere as little as possible with the free movement of the entire pipe line. A study of the shape of the entire line before and after expansion is the starting point. A designer with this information before him is in position to choose more intelligently the type of supports and to decide upon their position. The following types are suggested as showing the trend of recent design:

1 Long rods with turn-buckle adjustments
2 Spring supports on long rods
3 Counterweight supports on long rods
4 Spring supports on rollers
5 Cylindrical rollers (rollers with curvature to shape of pipe restrict movement)
6 Ball- and roller-bearing supports; see Carlier (Ref. *G*) for details.

b Anchors. Anchors serve two main purposes:

1 They avoid excessive thrust on apparatus such as turbines, boilers, and tanks
2 They avoid excessive displacements of the pipe line on expansion.

If an anchor does not directly serve one of these purposes, it should not be used. In cases of doubt it is suggested that the use of a limited-travel-type anchor will allow some movement and also insure that the amount of movement is within the desired limits.

The distance between an anchor and the apparatus which it is desired to protect should be as small as possible, since the apparatus must absorb the expansion of the length of pipe between itself and the anchor. Otherwise sufficient flexibility must be provided between the anchor and apparatus to keep the reactions within the allowable values.

C—PROPOSED DESIGN DATA

Fig. 16 is proposed to replace the values commonly quoted in handbooks and catalogs (Reference *E*), which now appear to be incorrect in several points and to have no rational basis. The proposed values make possible the computation of stresses and reactions, for given deflections, by means of a simple slide-rule operation, taking certain constants from the curves of Fig. 17. Solutions for other shapes than those given may be obtained, as were these, from the data given in Part III.

Illustrative Problem. Taking a 12-in., 000-lb standard pipe with fixed ends, and, for simplicity Case V of Fig. 16,

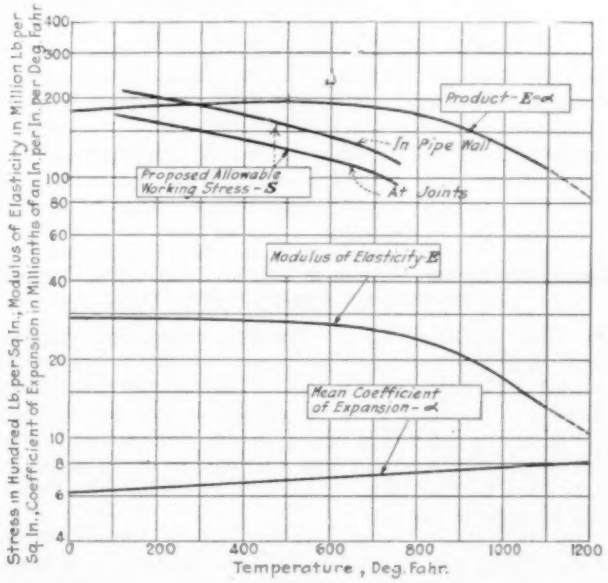

FIG. 20 ALLOWABLE STRESS, MODULUS OF ELASTICITY, AND COEFFICIENT OF EXPANSION FOR MILD STEEL PIPING

(Proposed allowable-working-stress curves are parallel to the proportional limit by French (Bur. Std. No. 296). Coefficient of expansion from Marks' Mechanical Engineers' Handbook. Modulus of elasticity from Trans. A.S.M.E., vol. 46, p. 405.)

O.D. = 12.75, t = 3/8, r = 6.06, temp. rise = 750 deg. fahr.
Assume $R = 6D$ = 72 in. I = 437 $E = 29\ (10)^6$
$\lambda = 1.225$ $K = 1.50$ $\alpha = 0.0000065$
From Fig. 17*a* $\mu_1 = 127{,}600$ $\Delta = 0.995$ in.
$\mu_2 = 6{,}370$

$$M_0 = \frac{0.006\ \mu_1 \Delta I}{K} = 222{,}000 \text{ lb-in.}$$

$$F_s = \frac{0.00098\,\mu_2\,\Delta I}{M} = 1810 \text{ lb.}$$

$\beta = 2.22$

Max. stress $= Mr\beta/I = 6840$ lb. per sq. in.

If the pipe be cold sprung to the extent of one-half the expansion, the reactions and stresses are all reduced one-half. This computation, for the sake of simplicity, ignores the flexibility of tangents at the ends of the lyre. It is recommended that the effect of the tangents be considered in design.

Suppose, that, instead of being fixed, the ends are only 50 per cent fixed. An accurate solution can be obtained by using the theory of fixity given under Part III. An approximate solution will be obtained by assuming the moment proportional to the fixity which, of course, will reduce the stress to one-half

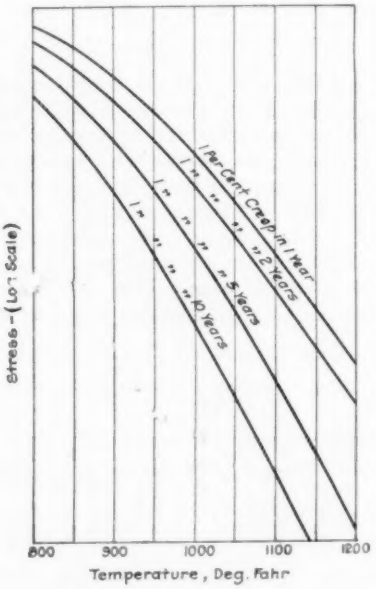

FIG. 21 SUGGESTED METHOD OF PLOTTING ALLOWABLE WORKING STRESSES ABOVE ABOUT 800 DEG. FAHR.

the value previously found. For more complicated cases of fixity, or in any case where an accurate solution is desired, the method of Part III should be used. The condition of fixed ends assumed in the figure gives the greatest stresses and reactions and should be assumed in case of doubt. Curves for the solution of partially fixed-end pipe lines may be drawn similar to those given for fixed ends. A few such curves for partial fixedness are given in Fig. 17*c*.

Fig. 18 makes it unnecessary to compute values of K for A.E.S.C. Standard Pipe when the radius of the bend R is between 6 and 10 times the mean diameter of the pipe cross-section. Intermediate values may be interpolated. Knowing the value of K from this figure, β can be easily obtained from Fig. 19.

It will be unnecessary to compute values of λ, since after obtaining the value of K from Fig. 18, the corresponding value of β will lie on the same vertical line in Fig. 19. Thus, from Fig. 18, the value of K for a 12-in., 600-lb. pipe with $R = 72$ in. is 2.21. Locating this value of K on Fig. 19, the corresponding value of $\beta = 2.26$.

Note that the value of β depends upon the curvature of the pipe at the point where M is taken. If the pipe is straight at this point, then $\beta = 1$; if not, it must be taken from the curve. For this reason the maximum stress in the pipe may occur in the curved section even though M does not reach its greatest value there. Hence, in case of doubt, the stress should be calculated using the greatest moment in the straight section with $\beta = 1$, and should be calculated again using the greatest moment in the curved section with the proper value of β.

The curves of Fig. 21 are intended to illustrate the suggested method of plotting allowable working stresses vs. temperature, and do not represent proposed values. Above some point (apparently around 800 deg. fahr. for carbon steel) creep phenomena take place and allowable stresses depend entirely upon the life desired, that is, upon economic considerations. Having set the maximum amount of creep at which the piping is to be retired, say, 3.0 per cent, the allowable stresses can be quickly obtained from such data as proposed above. A stress chosen from the "1 per cent creep in 5 years" curve would then mean that the piping should be retired in 15 years.

D—Typical Study of Shape Efficiency

For this brief study, three types of pipe lines are considered: Cases V, VIII, and X of Fig. 16. In all three cases we shall assume a constant total length of pipe of 884 in. and a constant horizontal length $L = 576$ in. Case V will then have a radius of 46.7 in. and straight portions of 222 in. on each end. Case VIII will have a radius of 72 in. and straight portions of 144 in. on each end. Case X will have a radius of 72 in. with no added length at the ends. An 8-in., 600-lb. standard pipe with fixed ends is used.

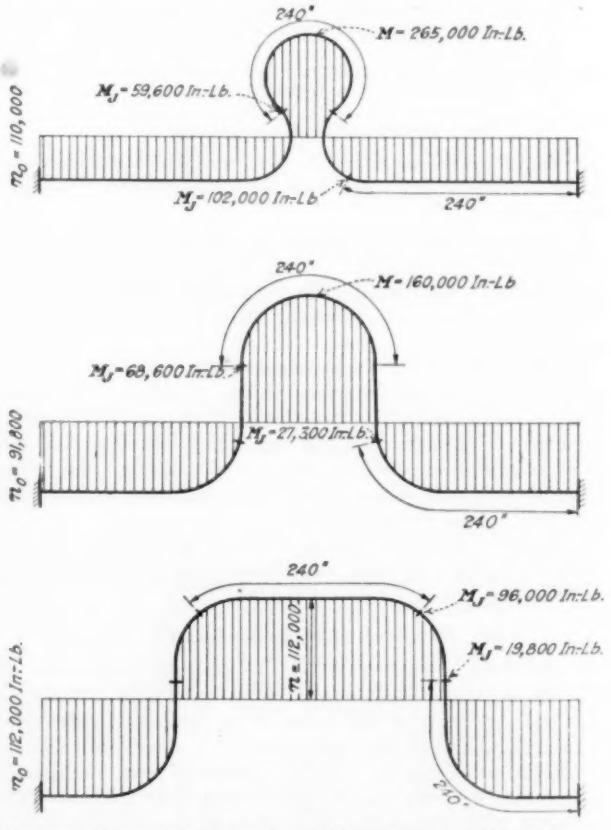

FIG. 22 TYPICAL STUDY IN SHAPE EFFICIENCIES OF PIPE LINES

Fig. 22 shows each case with neutral axis and location of maximum moments. In order to determine conditions at the joints of the pipe, a 20-ft. length of pipe has been assumed and the moments at the joints have been calculated. These are also shown in Fig. 22.

The results show that of the types considered, Case X is the most efficient as regards maximum stress. With the assumed pipe length Case VIII gives the least moment at the joints.

Conclusions

An attempt has been made:

1 To arrive at the fundamental principles of design.

2 To present a complete mathematical theory of piping subjected to expansion.

3 To reduce the very complicated results to a simple usable basis in the form of a proposed code of practice.

It is hoped that this very complicated subject has been reduced to such simple fundamentals as will enable designers to understand and visualize the design of steam piping to care for expansion much as they now do such simple elements as beams, so that much of the design can be accomplished by intelligent inspection of layouts on the drafting board.

It is the desire of the author to follow up the presentation of the data by checking it with interested persons against actual installations, and to cooperate in tests on full-size specimens so that a check may be made on the completeness of the theoretical analysis.

Acknowledgments

The great amount of tedious work involved in producing and checking this paper was performed chiefly by Messrs. H. E. Jenks, H. S. Keating, A. L. Porter, W. D. Washburn, and R. N. Williams, without whose cooperation the large amount of data presented would have been impossible. Acknowledgment is made to Mr. W. F. Ryan for valuable suggestions. The debt to authors of previous publications on the subject is obvious.

Discussion

A. Bantlin.[2] It would appear from the paper that along with many other important questions which have to be taken into consideration in the design of steam piping, the author considered the question of change of shape and stresses in the elastic pipe bends. I have already dealt with this question in the *Zeitschrift des Vereines deutscher Ingenieure*, 1910, p. 43 (compare also Forschungsheft No. 96). The tests on which that investigation was based were carried out with funds supplied by the V.D.I. In evaluating these tests, begun nearly 20 years ago, with the calculating methods then available, it is important not to forget that the investigation for the first time of a question as involved as that of highly curved pipe bends was very difficult. Not even then were equations for the change of shape of curved pipes established which would give values conforming to those obtained by actual measurements. The present paper corroborates my experience that the solution of a difficult scientific problem does not result from the first effort but from repeated endeavors. I came to this conclusion two years ago with respect to Professor Hovgaard's paper on "The Elastic Deformation of Pipe Bends," which came to my attention at that time.

Since my first investigation and report a number of German, English, French, and American investigators [compare (*B*) to (*K*), given in this paper] have successively dealt with the important problems which it involved, which is only natural if it is remembered that in the meantime the steam pressures and temperatures employed have greatly increased. Both of these factors have had a great influence on the design of complete piping installations as well as on the material and design of individual elements of the piping system. The renewed interest in elastic expansion members, an important element in piping systems, is therefore entirely justified. The mathematical treatment of the subject, as the author states, is quite a complicated matter, and, as any one who dealt with it knows, calls for a thorough knowledge of the matters dealt with; yet, in spite of the skill which has been applied, mathematical treatment has not given a specific solution of the problem. Notwithstanding the fact that the mathematical analysis has been to some extent simplified by various workers, among them the author himself, through the employment of curves and tables, these investigations, though they give a certain insight into the forces acting and the deformations produced thereby and indicate the measures which the engineer must employ in designing expansion equalization members and as a matter of fact the entire piping, still the fundamental problem has not been solved, namely, that of the actual as opposed to the calculated stressing of the pipe bends. As regards these actual stresses even today we are not yet in a position to draw reliable conclusions.

I might express the conviction that further extension of our knowledge regarding the determination of the actual magnitudes of the stresses must be expected mainly from further experimental work in which direct measurements of the actua! stresses in the bodies under test will be made. Instruments now available permit such direct measurement of stresses, and obviously a great step forward will be taken when it becomes possible to determine with certainty by test the true values of the maximum stress.

Such tests should be carried out only on pipe bends and piping of such dimensions and shapes as are actually used in commercial engineering, which means that none of these tests should be made on models.

I do not expect much from tests on models. In fact, the actual picture is likely to be falsified by such tests; that is, the results will never be exactly such as to make it possible to transfer reliably the data obtained from model tests to the design and construction of equipment for actual use. Tests of full-size commercial bends and piping require the expenditure of considerable sums, but are justified because of the valuable information which they afford designers and engineers.

Andrew A. Bato.[3] There has been written on the problem of temperature stresses in pipe lines material enough to fill a book; nevertheless the author has succeeded in summarizing what has been done in the past, and has also presented the results of his own work at the same time, the latter being a most valuable contribution to the theoretical as well as the practical handling of the design of steam pipe lines. This contribution is the theorem that the distance of the "line of zero moments" from an end is proportional to the fixity of that end, if the other end is hinged; also the application of the theorem to cases in which both ends are only partly fixed. To prove this theorem the author performed 44 series of experiments on 10 models, with 34 series out of the 44 on partly fixed models, all of them proving very closely the correctness and the usability of the theorem. By "fixity" the author designated what might be called "angular fixity." A further step will evidently be the introduction of "linear fixity," and the combination and influence of the two on each other. A good example of the connection between the two fixities is that of a pipe connected at one end to a main header. If the header is supported in such a manner that it will not bend nor yield to the linear expansion of the pipe line, the end of the latter will have a greater tendency to twist the header, as in the case in which the header can be twisted as well as bent.

Table 1 giving integrals for the various sections of pipe lines evidently also satisfies a demand felt in other quarters, as a proof of which the writer may mention that he too prepared a similar

[2] Professor, School of Technology, Stuttgart, Germany.

[3] Consulting Engineer, East Orange, N. J. Mem. A.S.M.E.

table while working for a public-utility corporation. The experience obtained at that time led him to point out that it should be impressed upon the minds of practical piping designers that this table has been derived by using the same methods, and is therefore just as reliable and is to be used in the same way as, for instance, the table in handbooks for the various cases of supported beams carrying loads.

In this connection it may be pointed out that the problem of temperature stresses has been worked out very elaborately for steel and concrete bridges, for simple arches as well as combinations resting on high columns, so that the bending of the latter has to be considered too, a case analogous to pipe lines with branches. The finest and most complete presentation of these problems in the American and English literature can be found in the books of Hool and Kinney on building structures. The circumstance that the temperatures to be considered in building structures are much lower than those occurring in pipe lines makes no difference in the mathematical methods. The loads in the case of bridges correspond to the weights of the pipe lines and their contents as well as the reactions of hangers, anchors, etc. The equations given in Part III, Section G, of the paper evidently cover these questions too, although the fact is not mentioned in the text.

In connection with the problem of the three-dimensional pipe line, that is, a pipe line in more than one plane, the writer made an experiment that in many cases may lead to a great reduction in the "very large amount of labor," mentioned by the author when dealing with this problem. As an example he took a pipe line consisting of three straight sections of different lengths, at right angles to each other, similar to that shown in Fig. 10 *c*. The case was assumed to be that of a pipe line with both ends fixed in every respect, angular and linear, and expanding under the influence of temperature. Six equations were developed, three corresponding to Equations [7] and [8] of the paper, that is, giving the linear deflections at one end as functions of the forces and moments acting at that end and of the elastic qualities of the pipe line; and three corresponding to Equation [9] of the paper, giving the three angular deflections at the same end of the pipe line in the three planes of the coordinate system, all set equal to zero, but otherwise on the same principle as the first three equations giving the linear deflections. The calculations naturally included the torsional deformations. The fact that pipes of a circular cross-section were assumed simplified the calculation somewhat, as for this case the polar moment of inertia to be considered for torsion is equal to twice the moment of inertia figuring in the bending. Furthermore the modulus of elasticity for shear used in calculating torsion is a fraction of the modulus for tension, consequently the members for torsion in the equations could be handled together with those for bending. The check that the calculations were correct was found in the fact that the resultant of the three forces was in the same plane as the resultant of the three moments. A little reflection shows that this could not be otherwise. The interesting fact about the result was that when the resulting force was combined with the resulting moment, which was made possible by the fact that they were in the same plane, the force thus shifted passed through the center of gravity of the pipe line. If it can be proved mathematically for every case that the resulting force, even when causing torsion, passes through the center of gravity or elastic center if both ends are fixed in every way, the work of calculating would be reduced to the solution of three equations.

A special merit of the paper lies in the thorough study of what has been done in the past, as a consequence of which the bibliography as known to the American public heretofore has been enriched by three works of fundamental importance.

The writer has not checked the formulas contained in the paper, partly because of insufficient time and partly because they had been checked as stated by the author.

The examples shown by the author seem to indicate that in most cases provisions for expansion in the general layout of the pipe line are preferable to the application of expansion bends. Nevertheless, even if expansion bends will be done away with, ordinary 90-deg. and 45-deg. elbows and bends will always be used in great numbers. A knowledge of the factor K for these bends is of a great importance in the design of pipe lines. As the value of this factor depends on the various methods of manufacturing it would be natural that the manufacturers would determine these values by experiments and publish them in their catalogs. Instead of doing this they have displayed lately, great indifference as to what has been going on in the development in the more correct methods of design, and all that has been produced and published has been due to the efforts and enthusiasm of those using pipe lines or designing them for their own use. These are the men who do the pioneering work, and the author has secured for himself the place of a leader with his work which he described in the paper.

HENRI CARLIER.[4] I am very much interested in the very fine work which the author has done, and it gives me real pleasure to make this humble contribution to its discussion.

GENERAL CONSIDERATIONS

In steam-piping installations it is advisable to take local conditions into consideration in determining a layout that will give sufficient flexibility. I agree with the author that so-called expansion bends should be used only under exceptional conditions. The flexibility of these devices is insignificant in comparison with that which can be obtained by considering the layout as a whole.

The supports and anchors can be determined only after a study of the layout. They should be designed so as to allow all movements resulting from the elastic deformation of the piping.

As to the problem of joints I cannot quite agree with the explanation given in the paper. The joints must be constructed so as to give perfect rigidity. The number of bolts must be sufficiently great. Joint leaks cannot occur then.

In other words, the joints should be tightened to such an extent that the stresses due to expansion will not further compress the packing material (metallic or metallo-plastic joint).

As far as possible pipe joints should be made near the inflection points (where the bending moment = zero). It will always be advantageous to utilize the elastic properties of the piping in the cold state by shortening it during erection, an amount which should be less than one-half of the expansion.

The author's solution of the problem of the flattening of curved parts does not appear to me quite correct.

In making a bend a so-called "ovalization" results, and during bending tests it will therefore pay to verify from point to point the various sections and to measure later the changes in shape of successive sections at the time when the bending stresses come into effect. In the expansion formula (elastic deformation) $\Delta = A/EI$, the decrease in I due to flattening corresponds to an increase in elastic flexibility.

The value of I depends on the care exercised in manufacturing. The bend may be more or less perfectly made (more or less irregular, with flat parts present).

On the other hand, if we consider a well-made and regular bend, we have the right to say that flattening under the effect of bending will occur at a point A, Fig. 23, near the point of tangency, and once this flattening has occurred there is no

[4] Engineer, Ressaix (Hainaut), Belgium.

reason why it should not be accentuated, if the expansion effects demand it. Therefore, as the writer sees it, the use of a coefficient $K = \varphi(\lambda)$ in which $\lambda = tR/r^2$ will not be sufficient to rectify the theoretical formulas.

To sum up the foregoing, the writer would recommend:

1 The use of thicker tubes.

2 The use of large radii of curvature (from 6 to 10 diameters). In this manner the tendency to ovalization at the bends will be reduced, and as a consequence uncertainties in computed results will be eliminated.

Fixing the ends of the piping diminishes the flexibility. Computations, however, should be made on the basis of thorough fixedness. If this is not entirely realized in practice, the flexibility will be greater than that computed and the safety correspondingly greater.

Method of Computation

The method of computation presented by the author is very elegant, but it seems to me difficult to derive therefrom formulas and construct diagrams for the use of designing draftsmen. In practice it is seldom possible to apply directly and simply formulas of elastic deformation derived from various well-determined cases. The conditions of the problem generally require a complete special analysis of the plans. In certain horizontal stretches following after vertical ones it is necessary to introduce bending due to the weight of the former. It is necessary, then, that those in charge of the design should have a perfect knowledge of the analytic theory.

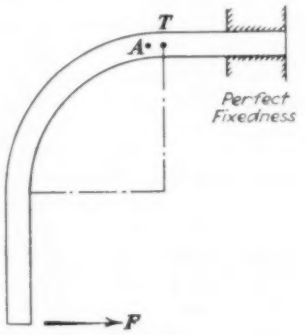

Fig. 23

In making the computations one must not make use of too optimistic hypotheses in order to protect oneself against surprises. On the other hand, it is less important to arrive, say, at the result that the intensity of stress S in the metal of the pipe is 3.755 kg. per sq. mm. (5340 lb. per sq. in.) than to the fact that $S<4$ kg. (5688 lb. per sq. in.).

The exact value to be assigned to E for high temperatures should be determined. Without having the exact data at hand, nevertheless I am under the impression that tests were made at a temperature of 450 deg. cent. (842 deg. fahr.) and that E was found to equal 16,000 (22,750,000) instead of 20,000 (28,500,000). The reduction in the value of E corresponds to an increase in flexibility. It is to be noted here, however, as the author says, that the elastic limit decreases with temperature and that, in consequence of this, the allowable stress S should be reduced in case of high pressures and high superheat temperatures.

Some Considerations as to the Installation of Steam Piping Systems

In spite of superheating, when the turbines stop running the steam condenses in the piping. To avoid the nuisance of trapped water during starting up, it is necessary to have the piping constructed with sufficient slope from the boilers to the turbines, so as to reduce the effect of low points forming pockets where the water due to condensed steam may accumulate.

In connection with this, a calculation of the sag produced by bending due to the weight of the piping (between two supports) will not be devoid of interest.

Let us consider a horizontal pipe resting on uniformly spaced supports of span A (Fig. 24a).

Let p be the weight of pipe per running meter.

At the middle of each span there will be produced a sag $f = \dfrac{pa^4}{384EI}$ with $\mu = \dfrac{pa^2}{12}$ and $\mu_M = \dfrac{pa^2}{24}$.

The spacing of the supports plays an important part. Indeed, let us suppose that for certain local reasons it has been decided to decrease the distance between certain supports (Fig. 24b) by shortening certain spans (i.e., $b>a$).

The conditions of resistance to bending can be improved while the sag will be found materially increased. Let us take the specific case defined by $b = {}^1/_2a$.

Let us designate the moments at A, B, and C, by μ_A, μ_B, and μ_C.

The theorem of three moments gives

$$\mu_A a + 2\mu_B(a + b) + \mu_c b = {}^1/_4 p\,(a^3 + b^3)$$

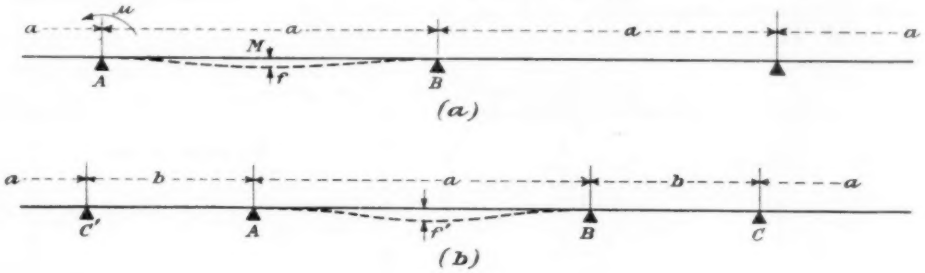

Fig. 24

but since $\mu_A = \mu_B = \mu_C = \mu$ and $b = {}^1/_2a$, therefore

$$\mu' = \frac{pa^2}{16}$$

Designating by $R = pa/2$ the part of the reaction $p(a + b)/2$ at A producing the deformation of AB, we have for AB (see Fig. 25),

$$\frac{d^2y}{dx^2} = \frac{\mu - p\,(a/2)x + px^2/2}{EI}$$

Integrating,

$$\frac{dy}{dx} = \frac{\mu x - (pax^2)/4 + px^3/6}{EI} + C$$

For $x = a/2$, $dy/dx = 0$ and $C = -\dfrac{\mu a/2 - pa^3/16 + pa^3/48}{EI}$

$$= \frac{pa^2/16 \times a/2 - pa^3/16 + pa^3/48}{EI}$$

$$= \frac{pa^3/96}{EI}$$

whence

$$\frac{dy}{dx} = \frac{\mu x - pax^2/4 + px^3/6 + pa^3/6}{EI}$$

and

$$y = \frac{\mu x^2/2 - pax^2/12 + px^4/24 + pa^3x/96}{EI} \text{ with } C' = 0$$

y is a maximum for $x = a/2$, and

$$y_{max} \text{ or } f' = \frac{(pa^2/16) \times (a^2/8) - pa^4/(12 \times 8) + pa^4/384 + pa^4/192}{EI}$$

$$= \frac{pa^4}{192EI}$$

we see that $\mu = pa^2/16 < pa^2/12$, and that $f^1 = pa^4/192\,EI = 2f$.

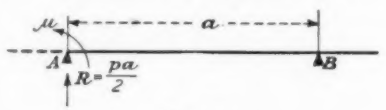

FIG. 25

These considerations suffice to demonstrate the importance of investigating the spacing of the supports.

Unsupported bends require a specially careful analysis also for the purpose of avoiding low points.

If one confines himself to the problem of resistance, it will be sufficient to impose the condition $\mu_C = \mu_A$, the tangents at B and B' (Fig. 26) being horizontal, and to seek for relations connecting a, b, and c.

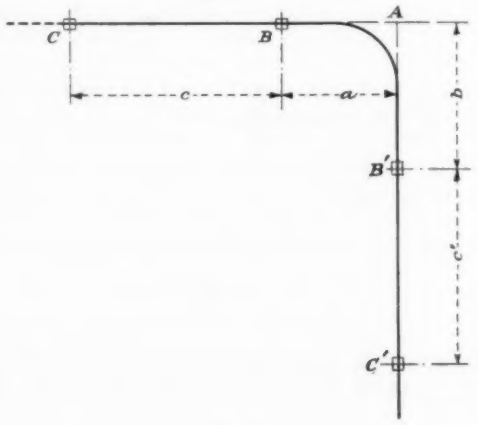

FIG. 26

The condition $a > b$ leads us to consider a stress P at the end of a and a reaction equal to P at the end of b.

The connection between a and b brings about fixedness at A (μ_A). Under the influence of μ_A, b is subjected to torsion.

The differential equation of the deformed length a (Fig. 27) is:

$$\frac{d^2y}{dx^2} = \frac{\mu_B - Rx + px^2/2}{EI}$$

Whence

$$\frac{dy}{dx} = \frac{\mu_B x - Rx^2/2 + Px^3/6}{EI} + C$$

($C = 0$ if we assume that at B, $dy/dx = 0$.)
For $x = a$,

$$\frac{dy}{dx} = \frac{\mu_B a - Ra^2/2 + pa^3/6}{EI}$$

Now at A the section suffers rotation caused by the torsion of the branch $b = \frac{5}{4}\frac{\mu_A(b-r)}{EI}$ in limiting b to the right-hand portion $b - r$; whence the equation

$$\mu_B a = -R\frac{a^2}{2} + \frac{pa^3}{6} = -\frac{5}{4}\mu_A (b - r)$$

μ_A takes its negative sign with respect to μ_A with the positive sign.

Analogous reasoning with reference to the branch b gives (P changes in direction—see Fig. 28):

$$Q = pb - P$$

$$\mu'_B b - Q\frac{b^2}{2} + \frac{pb^3}{6} = -\frac{5}{4}\mu'_A(a - r)$$

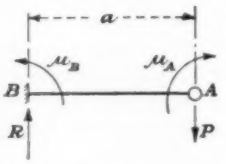

FIG. 27

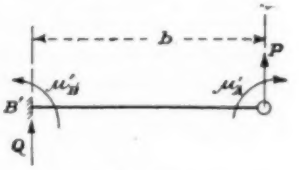

FIG. 28

The moment equations are as follows:

$$\mu_B - Ra + pa^2/2 - \mu_A = 0$$

$$\mu'_B - Qb + pb^2/2 - \mu'_A = 0$$

$$\mu_B = 1/12pc^2 \text{ and } \mu'_B = pc'^2/12;\ C > < C'$$

We finally obtain:

$$\frac{1}{12}pc^2a - (pa + P)\frac{a^3}{2} + \frac{pa^3}{6} = -\frac{5}{4}\mu'_A(b - r)$$

$$\frac{1}{12}pc'^2b - (pb - P)\frac{b^2}{2} + \frac{pb^3}{6} = -\frac{5}{4}\mu'_A(a - r)$$

$$\frac{1}{12}pc^2 - (pa + P)a + \frac{pa^2}{6} - \mu_A = 0$$

$$\frac{1}{12}pc'^2 - (pb - P)b + \frac{pb^2}{2} - \mu'_A = 0$$

The unknowns are μ_A, μ'_A, P, a, and b.

Eliminating μ_A, μ'_A, and P, there will remain an equation of a relation connecting a and b.

Under the above conditions ($dy/dx = 0$ for B and B'), what will be the value of vertical displacement of fictitious point A?

To solve this problem, a and b are imposed. The above equations permit determining μ_A and μ'_A.

The elastic equation of deformed part a is

$$\frac{d^2y}{dx^2} = \frac{\mu_B - Rx + px^2/2}{EI}$$

$$\frac{dy}{dx} = \frac{\mu_B x - Rx^2/2 + px^3/6}{EI}$$

$$dy = \frac{\mu_B x^2/2 - Rx^3/6 + px^4/24}{EI}$$

$$f_A = \frac{\mu_B a^2/2 - Ra^3/6 + pa^4/24}{EI}$$

NOTE. If either C or C' or both of these spacings, other conditions remaining unchanged, are decreased, the conditions of resistance will not be found materially modified, but the equili-

brium of moments will rapidly cause the descent of point A, manifestly creating a low point.

The section B and B', or both, are turned through an angle α, and, other conditions remained unchanged, point A consequently descends a supplementary distance αa. It will be advisable to give the pipes a slope as shown in Fig. 29. Here J and K are joint flanges. For the drilling of bolt holes, it should be noted that flange K must be turned with reference to J through an angle corresponding to the inclination of branch AB'.

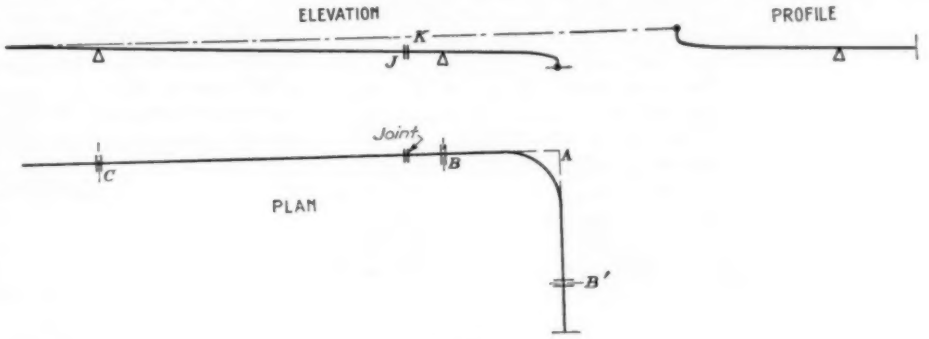

FIG. 29

SPECIAL SUPPORTS

Figs. 30–32 show three types of support. Fig. 30 shows a support (suspension) for a horizontal pipe at a point relatively close to the vertical branch $a > h\alpha T$ so that the pipe will still have a slope after the expansion of the vertical branch; α is the coefficient of expansion. The spring (shown enlarged at the right of Fig. 30) must be designed to have great flexibility in order to absorb the expansion and balance it against the dead weight suspended.

Fig. 31 shows a swivel-joint support for the vertical branch of a piping system having five branches, a, b, c d, and h. The swivel joint permits:

1 Torsion of branch h under thrust of branches a and b.

2 Rotation with bending in plane MN under thrust of $b(b>a)$ and at the same time in a plane resulting from the effect of the expansion of c and d. a and b may not be in the same plane; in this case a and b do not afford the same flexibility for absorbing the expansion of branches c and d.

Fig. 32 shows a support for a horizontal pipe which permits rotation in every direction.

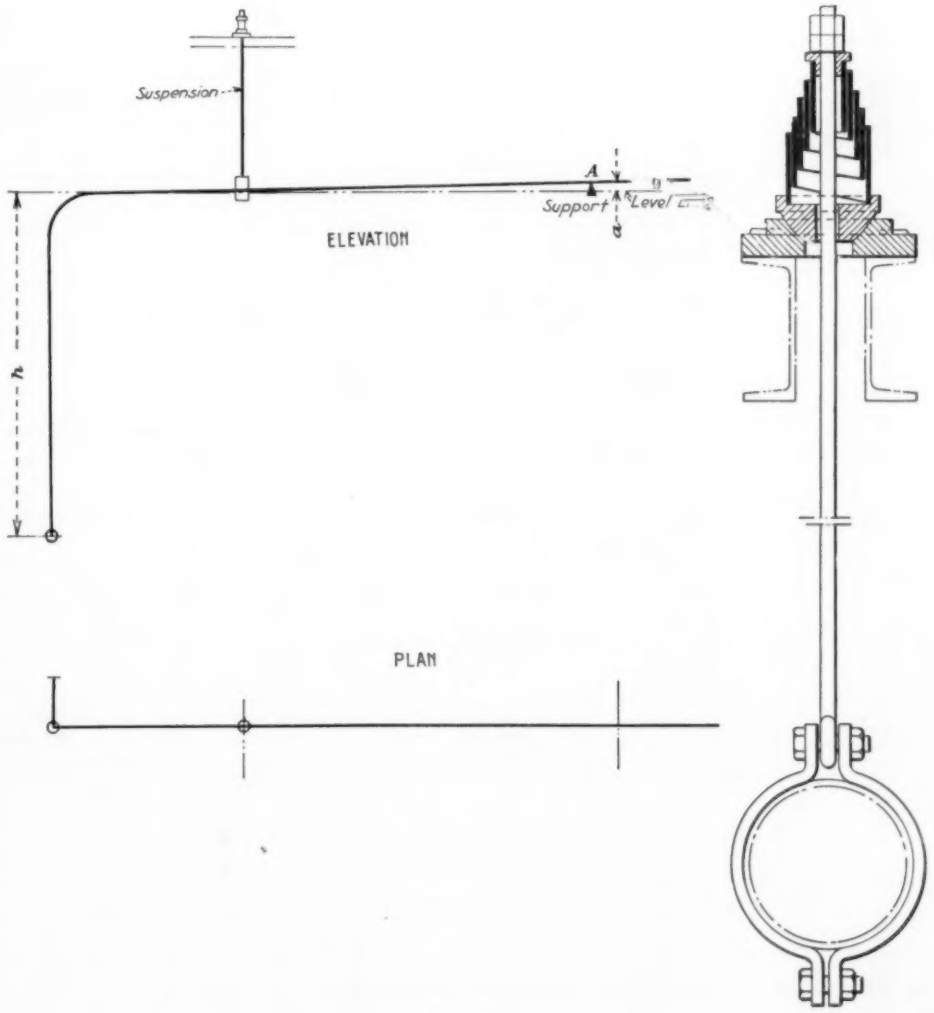

FIG. 30

LETTER FROM HENRI CARLIER

I have received and studied the very interesting paper which you presented at the Annual Meeting in New York last December.[5] Difficulties which I encountered in translating it and also the short time between the Annual Meeting and the time I received your letter prevented me from entering into the discussion to the extent that I desired, nevertheless I sent to the meeting a brief communication of which you are undoubtedly aware. In that discussion I stated that it seemed to me to be difficult to work out a method that would be useful to designers. I would now recall that statement and inform you that I have succeeded in finding a simple method which permits solving all the curves considered in my 1925 book. You are of course aware of the enormous amount of work which I have done in the last few years in connection with the study of elastic deformation of steam piping. Within the last few months I have studied Mr. Marbec's method and have come to utilize the single point

[5] Letter from Mr. Carlier to the author dated March 7, 1929.

and the central force (resultant of internal elastic force) but without finding it necessary to look for the axis and the *principal* moments of inertia.

The different formulas of my 1925 book, with the exception of formulas [55], [58], [66], and [72], have been checked by the new method. This applies to such cases as that shown in

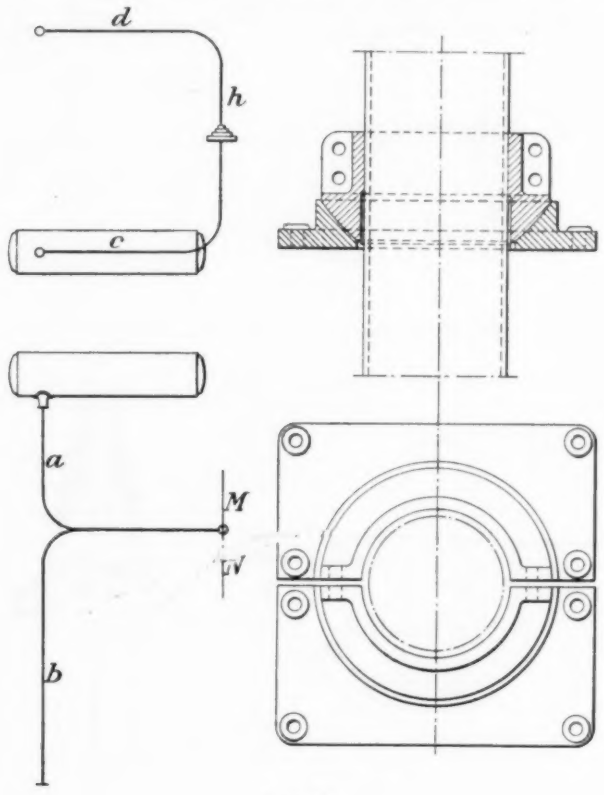

FIG. 31

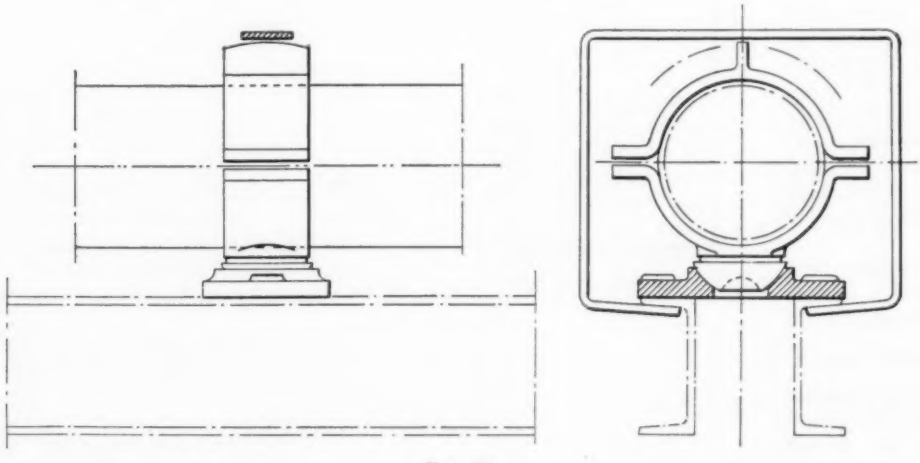

FIG. 32

Fig. 33 in which h is smaller than the sum of the transverse elements.

Integration leads to the formulas referred to above, but the general formula

$$\Delta y = \int (x_1 - x)\frac{M}{EI}\,ds$$

cannot be applied here because the branch C reenters into the curve.

FIG. 33

As to what I said in reference to formula [56], p. 93, Fig. 52, of my book of 1925, let us take the following example, formula [64] (see Fig. 34):

Formula [66] gives $106.09\,P' - 28.75\,P = h\alpha T$. This expression is erroneous. My new method gives directly

$$\frac{1}{EI}(109.08\,P' - 7.75\,P) = h\alpha T$$

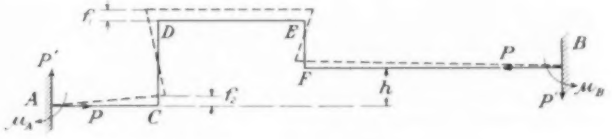

FIG. 34

and I have verified it by the Marbec method. Moreover it can be verified by the following analytic solution:

Referring to Fig. 35, let us consider separately

1 The elastic system AC, in which the transverse displacement of $C = f_2$, and

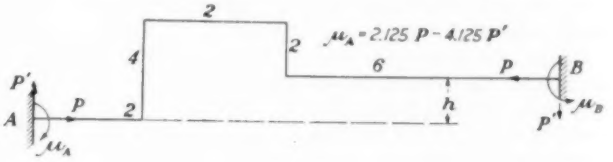

FIG. 35

2 The system $BFED$ in which the transverse displacement of $D = f_1$.

$$f_1 - f_2 = h\alpha T$$

$$f_2 = \frac{1}{EI}(4.25P + 6.91P') \quad f_1 = \frac{1}{EI}(102.17P' - 3.5P)$$

$$f_1 - f_2 = \frac{1}{EI}(102.17P' - 3.5P - 4.25P - 6.91P'), \text{ and}$$

$$\frac{1}{EI}(109.08P' - 7.75P) = h\alpha T$$

I have thought that considering the value of the results of my investigation, it should be possible for me to obtain some return therefor. I am now engaged in revising my new notes. These latter will not be published, but a limited number of copies will be reproduced for the use of Belgian and French designers to whom I shall offer my method and for a certain subscription price. Possibly there may be engineers in the United States who would like to avail themselves of the same opportunity. In this new work I show that the central point is the center of gravity of the curves in the case of piping fixed at both ends. I also show how the central point is displaced when one of the extremities turns through a certain angle (case studied in my pamphlet published in 1927).

ELBERT C. FISHER. With the high pressures and temperatures now being used in modern practice, it is very essential that the piping system should be designed so that the anchors may be reduced to the minimum, and that the system be made as flexible as possible without imposing excessive strains at any point in the system.

With the amount of theoretical data, as well as the results of tests that have been made in the last ten years and presented before the Society at various times, the proper design of a piping system, based on the above data, must be worked out by an engineer well acquainted with this subject, as well as equipped with a good knowledge of mathematics.

The author's paper makes his theoretical analysis available for the practical problems encountered in design of piping systems.

Fig. 16, for finding bending moments for various bends with fixed ends, is not of much value in power-house piping design, but would be of greater value in finding the stress in flanges for short-length bends connecting various parts on the same piece of apparatus, or sometimes where the connections between pieces of apparatus are placed closely together.

With the type of flanges used in the present design for high-pressure service, the stresses in the flanges are usually very small; that is, if the piping layout is properly designed.

The writer has taken a considerable interest in the articles regarding the flexibility of pipe that have appeared from time to time. However, the four articles by J. R. Finniecome published in *The Engineer* (London), August 17, 24, and 31 and September 7, 1928, seem to have covered this problem in a most thorough and practical manner.

Mr. Finniecome, after a thorough investigation, has adopted Karman's theory and in the last article he gave a table of formulas which also includes the Karman correction formulas. These formulas, given herewith in Table 5, are such that a power-house designer can easily determine the thrust and strain which will occur in a power-house piping system.

If, in some cases, Mr. Finniecome's analysis should slightly disagree with the exact theory, the writer nevertheless believes it could be considered as close enough for all practical purposes for checking any piping system.

In order to simplify Mr. Finniecome's analysis, the writer has prepared Table 6, which gives Karman's correction factors to be used for the different standard sizes of pipe ranging from 4 in. to 20 in., and based upon a radius of six pipe diameters for bends.

Δ_K = Karman deflection.
K_H = Karman deflection, thrust correction factor.
H = force producing deflection due to temperature change.
$\varphi = \delta R/r^2$ = pipe factor.
K_s = Karman deflection-stress factor.
f_b = theoretical longitudinal bending stress due to thrust.
$1/K_T$ = Karman stress-thrust correction factor.
K_T = Karman thrust-stress factor.
H_K = Karman thrust.
f_{bK} = Karman longitudinal stress.
$[f_{bK}]_{l_1}$ = transverse stress at top of outside diameter of cross-section for y_{max}.
$[\psi r_1]_l$ = Z—transverse stress factor for $Z = r_1$.
Z = distance from neutral axis.
$1/[K_T]_{l_o}$ = ratio of transverse bending stress at neutral axis to theoretical longitudinal stress.
$[f_{bK}]_{G_1}$ = combined Karman stress at top of outside diameter of cross-section.
y_{max} = maximum normal distance of arc element from direction of thrust.
R = radius of pipe bend.
d_1 = outside diameter of pipe.
d = bore of pipe.
r = mean radius of cross-section.
δ = wall thickness of pipe.
I = moment of inertia.

$$\left.\begin{array}{l}\text{Theoretical deflection thrust factor} = C_H = \dfrac{\int y^2 ds}{R^3} \\ \text{Theoretical deflection stress factor} = C_S = \dfrac{\int y^2 ds}{y_{max} R^2}\end{array}\right\} \text{for bends consisting of an arc or a number of arcs of the same mean radius}$$

$C_T = C_S/C_H$ = theoretical thrust stress factor.

$1/[K_T]_G$ = ratio of Karman combined stress to theoretical longitudinal stress for $z = r$.

W. Hovgaard.[7] The paper covers practically the whole field of the design of pipe bends, and should prove of great value to practical engineers.

[7] Professor of Naval Design and Construction, Massachusetts Institute of Technology, Cambridge, Mass.

Fundamental equations for the calculation of deflections, moments, and reactions in plane pipe lines are given and are applied to a great number of specific cases. The value of the integrals which enter into the calculations are tabulated, but the formulas given for the more general cases on the sixth and seventh pages seem rather cumbrous, and it is believed preferable there to use graphical methods. It may not be out of place to remark that the same problem is discussed in a general way in a paper just published by the writer.[8]

In the discussion of stresses in ductile materials, the author gives preference to the formulas of Professor Lorenz on account of their simplicity. It seems, however, that since these formulas disregard the flattening of the pipe section and assume the stresses to be proportional to the distance from the neutral axis, they cannot be correct. The author makes use of the maximum shear theory in calculating the "equivalent" stress, as does also Mr. Wahl in his investigation. According to this theory the criterion of strength is the difference between the algebraically greatest and smallest principal stresses, while the middle stress is assumed to be without influence on strength. This theory has been shown in recent years to be not quite correct, and a new formula has been proposed by Dr. H. Hencky[9] and others. This formula is based on the principle that plastic flow occurs when the elastic work of deformation (not including the volume strain) reaches a certain constant value, whatever be the stresses by which it is produced. In two-dimensional stress as in the wall of pipe bends, flow will occur according to this theory when:

$$S_1^2 - S_1 S_2 + S_2^2 = S_0^2$$

where S_0 is the yield point of the material. Thus, according to this theory, the equivalent stress is equal to the square root of the expression on the left-hand side of the equation. This theory has found excellent confirmation by various tests, notably by those made in Zürich by Professor M. Ros and A. Eichinger.[10]

Quite recently the writer has made tests on pipe bends of 6-in., 9½-in., and 14-in. diameter, with the special object of determining the stresses in the pipe at the point where a permanent set occurs in the bends. It was hoped in this way to obtain a criterion for the strength of pipe bends which can be used in practice with a factor of safety as determined by experience. Measurements were made of the deflection of the bends, that is, the approach of the bends to each other; the stresses were determined on a section at the top of the bend where the bending moment was a maximum. The longitudinal strains were measured directly with Berry strain gages; the transverse strains were computed from measurements with a micrometer caliper of the diameters all around the pipe section. The stresses were calculated by taking into account both longitudinal and transverse strains from the formulas:

$$S_1 = \frac{m^2 E}{m^2 - 1}\left[\epsilon_1 + \frac{\epsilon_2}{n}\right]$$

$$S_2 = \frac{m^2 E}{m^2 - 1}\left[\epsilon_2 + \frac{\epsilon_1}{n}\right]$$

where ϵ_1 and ϵ_2 are the observed strains and m is Poisson's constant. The "observed" stresses so determined were compared with the "calculated" stresses obtained by the theoretical formulas. Also the equivalent stress, using the Hencky formula as well as that of the maximum-shear theory, was calculated.

[8] W. Hovgaard, "Deformation of Plane Pipes," *Jl. Math. and Phys.*, Mass. Inst. Tech., vol. 7, no. 3, October, 1928.

[9] *Zeitschrift für angewandte Mathematik und Mechanik*, Bd. 4, Heft 4, 1924.

[10] Second International Congress of Tech. Mech., Zürich, 1926.

It was found, contrary to expectation, that at the load where the pipe began to show a measurable permanent set, the transverse as well as the equivalent stresses were far in excess of the limit of plasticity. Evidently none of these stresses could be used as a criterion of strength. It must be noted that the transverse and equivalent stresses exist only on the surface and extend at first over limited zones, so that they cannot be expected to influence the behavior of the bend as a whole until the zones of plasticity have spread over greater areas and to greater depth below the surface.

The longitudinal stresses, on the other hand, were just within the limit of elasticity when the bends began to show a permanent set, whence it would appear that these stresses, which exist with moderate variations throughout the whole thickness of the pipe wall, might serve as a measure of strength. The tests, however, are not considered sufficiently comprehensive to justify this generalization. They covered a relatively limited range of λ values, comprising only pipes for moderate steam pressures. Further tests are required, notably tests on pipes for high pressures, say, 500 lb. per sq. in.

A full description of the tests here referred to and their analysis will shortly be published in the *Journal of Mathematics and Physics* of the Massachusetts Institute of Technology under the title, "Further Research on Pipe Bends."

HAROLD E. JENKS.[11] The paper presents a very complete collection of exact formulas and is unique in that the solution of a one-plane pipe line of any shape is reduced to a practical problem.

The first fundamental principle given in the paper—that the entire pipe line (between anchors) is carrying the expansion and that the use of expansion bends should be the exception and not the rule—is finding increasing application in modern design. Hence in the future we may expect to analyze fewer conventional bends and more odd shapes, partly curved and partly straight. Table 1 and Formulas [13] to [22], inclusive, provide a solution for the reactions in any one-plane pipe line with fixed or hinged ends. These formulas, together with formula [2], which enables the maximum moment to be found, and formulas for the flexibility constant K and for stress are all that are needed.

The point that in practice the ends of pipe bends are usually more nearly fixed than hinged is of extreme importance. With the exception of Carlier's notable work and one or two examples in Wahl's article, all mathematical analyses which the writer has seen up to the present time have ignored this important factor. Under fixed-end conditions the maximum stresses in a pipe line may be as much as 50 per cent greater than under hinged-end conditions and at an entirely different point in the line. The reactions may vary even more than this. Hence, where any doubt exists as to the amount of fixity of the ends, they should be assumed fully fixed so that a variation from these conditions will result in an error on the safe side. Hinged ends make excellent test specimens as their analysis may be relatively simple, but they are of infrequent occurrence in design. A series of articles by Mr. Finniecome recently published in *The Engineer* (London) contains much valuable information, but here again all calculations are based on hinged-end conditions. The same disregard of end fixity leads him to what are probably erroneous conclusions regarding the value of the flexibility constant K, as will be explained below.

The values of the flexibility constant K and corresponding stress formulas as obtained to date by various methods of analysis are presented by the author, Mr. Shipman, who adopts the Lorenz formulas in his work. According to the Lorenz theory, the longitudinal stress in the curved portion of a pipe bend is proportional to the distance from the neutral axis—a straight-line distribution. This does not, however, mean that flattening of the pipe has been disregarded, since the moment from which the stress is found is a function of the flexibility constant. The Karman theory, on the other hand, results in a longitudinal stress which has not a straight-line distribution. Because of the apparent verification by Professor Hovgaard of the Karman distribution of longitudinal stress, the writer believes that the Karman theory represents the closest approximation to the conditions actually obtaining in practice. The Karman flexibility constant $\frac{10 + 12\lambda^2}{1 + 12\lambda^2}$, as at present used, is admittedly erroneous for small values of λ. Karman's second approximation,

$$\frac{3 + 536\lambda^2 + 4800\lambda^4}{105 + 4136\lambda^2 + 4800\lambda^4}$$

is better, but for small values of λ still gives results that are considerably too low.

The necessity for analyzing several pipe lines where λ was approximately 0.05 recently led the writer to extend the Karman theory to cover such cases; in other words, to find the nth approximation. The theory is much too involved for presentation here, but the result may be expressed as follows: For all values of λ the true value of the Karman flexibility constant is given by

$$K = \frac{10 + 12\lambda^2 - j}{1 + 12\lambda^2 - j}$$

where j is a complex function of λ varying from unity when $\lambda = 0$ to zero when $\lambda =$ infinity. The numerical value of j may be found to any desired degree of accuracy by obtaining the ratio of two determinants of the nth order and is given in the following table:

λ...	0	0.05	0.1	0.2	0.3	0.4	0.5	0.75	1.00
j...	1	0.7625	0.5684	0.3074	0.1764	0.1107	0.07488	0.03526	0.02026

The error due to using the formula $(10 + 12\lambda^2)/(1 + 12\lambda^2)$ instead of the true value amounts to 72 per cent when $\lambda = 0.05$, 7 per cent when $\lambda = 0.3$, and 1.2 per cent when $\lambda = 0.5$. For values of λ greater than 0.5 the error is less than 1 per cent, hence the formula $(10 + 12\lambda^2)/(1 + 12\lambda^2)$ is sufficiently accurate for such values.

A curve plotted from the above table will enable intermediate values of j to be found with accuracy; hence the true curve of K for all values of λ may also be plotted.

The true value of K as given above is in approximate agreement with Mr. Finniecome's suggested value for values of λ less than unity. The Crocker and Sanford data used by Mr. Finniecome in arriving at a suggested curve for values of λ greater than unity have been shown by the author to represent a probable fixity of from 7 to 46 per cent, which would account for Mr. Finniecome's test curve falling below the true curve. The quantity, and with few exceptions the quality, of available test data do not in the writer's opinion warrant a definite statement that the value of K by any theory has or has not been checked.

The more complete theory also requires the derivation of new stress formulas, taking into account the effect of longitudinal and transverse strains according to the theory of elasticity. For values of λ above 0.5, the following formulas give the true stresses:

Longitudinal stress at outer surface of pipe

$$S_1 = \frac{KMr}{I}\left[\sin\phi + \frac{4K - 4}{K}\left(\frac{\lambda}{2m}\cos 2\phi - \frac{1}{3}\sin^3\phi\right)\right]$$

[11] Atmospheric Nitrogen Corporation, Syracuse, N. Y. Formerly Assistant Professor of Mathematics, U. S. Naval Academy.

Transverse stress at outer surface of pipe

$$S_2 = \frac{KMr}{I}\left[\frac{\sin\phi}{m} + \frac{4K-4}{K}\left(\frac{\lambda}{2}\cos 2\phi - \frac{\sin^3\phi}{3m}\right)\right]$$

Longitudinal stress at middle surface of pipe

$$S_3 = \frac{KMr}{I}\sin\phi\left(1 - \frac{4K-4}{3K}\sin^2\phi\right)$$

In these formulas ϕ is the variable angle of the pipe cross-section, being zero at a distance R from the center of the pipe bend and 90 deg. at a distance $R + r$ from the center, and m = the reciprocal of Poisson's ratio, usually taken as 10/3 for steel. The value of ϕ for a maximum value of stress can be found by differentiation with respect to ϕ. Construction of curve sheets will facilitate the use of these formulas.

For values of λ of 0.5 or lower the above formulas or any heretofore published are not sufficiently accurate. In such cases the exact formulas are very complicated and will not be presented here, but values computed from them are given in the following table from which curves may be plotted:

λ	0.05	0.1	0.2	0.3	0.4	0.5
K	34.6	17.31	8.68	5.73	4.20	3.29
C_1	7.94	4.97	3.10	2.33	1.864	1.557
C_2	13.61	8.47	5.24	3.94	3.19	2.675
C_3	6.34	3.99	2.51	1.877	1.500	1.260

The maximum values of S_1, S_2, and S_3 are given by $C_1\frac{Mr}{I}$, $C_2\frac{Mr}{I}$, and $C_3\frac{Mr}{I}$, respectively.

Professor Hovgaard's recent valuable experiments indicate that S_3 may be the true criterion of pipe strength rather than "equivalent stress" as heretofore used, and he tentatively recommends that this stress be kept below 20,000 lb. per sq. in. for a cold pipe. The maximum value of S_3 for $\lambda > 0.5$ is given by

$$S_3 \max = \frac{KMr}{3I}\sqrt{\frac{K}{K-1}} \text{ when } K > \frac{4}{3}$$

$$= \frac{Mr}{I}\left(\frac{4-K}{3}\right) \text{ when } K < \frac{4}{3}$$

which with the values of C_3 given above would, under this criterion, make limiting stress calculation a relatively simple matter.

C. T. Mitchell.[12] Since the author expresses a desire to aid in promoting the practical application of the theories presented in his paper, he will be interested to know that a graphical method of analysis, identical in theory and similar in application to the one he briefly outlines, has been for some time in active use in one of the offices in New York City. The method was developed from formulas which the writer published about eighteen years ago[13] for the determination of neutral axes in rigid framed structures. As applied to pipe structures, it proves surprisingly simple. The pipe between anchors is laid out to scale, with square corners substituted for the bends. The ends are assumed to be fixed, which requires, as the author points out, that the axis of zero bending moment shall pass through the center of gravity of the structure. This axis is laid out and the bending-moment diagram plotted for each straight member, the member itself forming the central axis of the diagram. The sum of the areas of all the moment diagrams times the distance of the center of gravity of each from the neutral axis supplies the only unknown quantity necessary to determine the thrust at the anchors or the bending stress at any point in the structure. A correction is finally made to allow for the bends by multiplying the computed thrust by the ratio of the length of assumed square-cornered structure to the length of the actual structure with round corners.

A simpler method than this for attaining anything like accuracy is hardly possible. It requires no tables or formulas other than those necessary to compute the moment of inertia of the pipe section. In the stress of production which prevails in most work, it is a veritable time saver. Most pipe structures are changed a dozen times in the course of design. Sometimes a small change in dimensions has a serious effect on the expansion stresses. Elaborate recalculation with each shift in design is not practical. The graphical method, being rapid in execution, aids the designer in acquiring a valuable sense of proportion.

So much for the practical aspect of this graphical method. Its limitations as to accuracy appear to be the following:

In always assuming 100 per cent rigidity at the anchors, it sometimes indicates greater rigidity in the structure than actually exists. But the results are on the side of safety.

It takes no account of the increased flexibility of bent over straight pipe. In this respect the results are again on the side of safety. It is not accurate for certain structures composed entirely of bends. However, structures of this nature are extremely rare in practice. By far the major part of power-plant piping is made up of straight lengths connected by bends or fittings.

In other words, the graphical method appears to sacrifice a small amount of accuracy in favor of uniformity and simplicity. High degree of accuracy in problems of this nature is, of course, unattainable, due to the uncertainty regarding the rigidity of the anchors and also as to the amount of flattening of cross-section that occurs in the bending of the pipe. To be on the safe side in these matters requires a little more pipe, the cost of which is probably negligible.

The writer would very much like to learn the author's opinion regarding the allowable stress on a pipe joint. In the diagram, Fig. 20, of the paper, the author submits a curve giving proposed allowable working stresses at pipe joints ranging from 10,000 to 20,000 lb., according to temperature. It is assumed that this refers to the stress in the pipe at the joint. These figures seem very high. The writer would suggest that in high-pressure work (600 to 1200 lb.) the pipe stresses at the joints due to bending be maintained at not over 5000 lb. per sq. in. for temperatures above 700 deg. fahr.

A. M. Wahl.[14] The writer believes the present paper to be a valuable contribution to the literature on the design of steam piping. The various principles enumerated on the first page deserve special recognition because of their importance. Principle No. 2, which states that supports and anchors should be placed so as not to restrain free movement of the pipe line, is especially important, while the limited-travel anchors mentioned may be of very great help in eliminating undesirable reactions in many practical cases.

It is the writer's belief that the Karman theory as developed in his previous paper[15] will give results more nearly in accordance with actual pipe-bend test results than either the Lorenz or Marbec theories. He bases this opinion on the following facts: Karman derived his formulas in a rational manner, using Ritz's method of specifying the deformation of the cross-section in the

form of a trigonometrical series with undetermined coefficients and later determining these coefficients to make the potential energy a minimum. Lorenz, on the other hand, used an approximate method and obtained a straight-line law of longitudinal stress distribution over the cross-section. This type of stress distribution, however, is not correct, as is shown experimentally by the strain measurements on actual pipe bends both by Hovgaard and the writer. Strain measurements made by the writer on 10-in. diameter turbine expansion pipe bends in collaboration with the South Philadelphia Works of the Westinghouse Com-

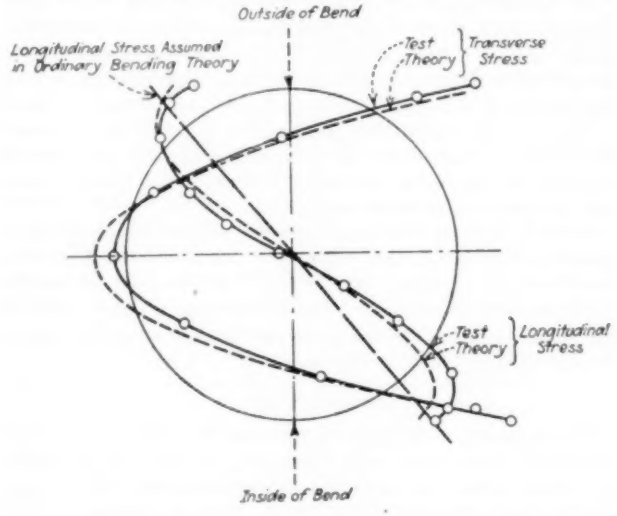

FIG. 36

pany give a stress distribution over the pipe cross-section as shown in Fig. 36. The full lines show the stress distribution found by test, while the dotted lines show that calculated theoretically using the Karman theory and its development by the writer. It may be seen that the distribution of stress closely follows the Karman theory, while the linear law given by Lorenz is entirely incorrect.

A further reason for believing the Karman theory to be more nearly correct than the Lorenz theory is given by the values of k found by the writer in the paper mentioned above. In Fig. 37 the curves of Fig. 13 of the paper have been replotted, and the experimental points obtained by the writer indicated. It may be noted that these points follow the Karman curve very closely. The author states that the writer's data "were not plotted because of uncertainty as to end conditions of curved portions." However, the writer cannot see where any uncertainty exists.

In his tests the U-bends were loaded as shown in Fig. 38. There was practically a hinged-end condition at the ends of the U-bend at c and c' because of looseness in the clamps attached to these points. Hence, at the ends b and b' of the curved portions, we have practically a moment Pa acting plus a direct load P. Under these conditions the loading at the ends b and b' is completely defined. The deflection between these points may then be computed, using the formulas for Cases 4 and 6 in the writer's paper.[14]

It should also be noted that the chart given by the writer in Fig. 25 of his paper for equivalent stress in curved pipes was also given later by Finniecome.[16] However, it must be realized that there is not a great deal of difference between the values of stress and deflection given by the Karman and Lorenz formulas. This is apparent by reference to Figs. 7 and 13 of the author's paper.

In the manufacture of pipe bends there is also produced an initial ellipticity of the pipe cross-section. This ellipticity, though small, is nevertheless sufficient to greatly change the stress distribution produced by internal pressure. Tests made by the writer in collaboration with the South Philadelphia Works of the Westinghouse Co. show that where the ellipticity of the cross-section of a 10-in. pipe bend is as small as $^1/_8$ in., the bending caused by internal pressure may be sufficient to induce compressive stresses at certain points on the outside of the pipe wall. At other points, under these conditions, stresses equal to twice the direct stress produced by internal pressure may arise. The stress set up by this initial ellipticity of the pipe bend may be approximately computed by using formula [49] of the writer's paper, remembering that M_0 is the bending moment per inch length. Hence, the stress is

$$S = \frac{6\,M_0}{t^2}$$

where t is the thickness of the pipe wall. This stress due to bending must be superimposed on that due to direct circumferential tension.

When this stress, which may be quite high, under the increasingly high steam pressures now coming into use, is superimposed on the stresses due to bending moments, flattening of the cross-section, etc., the resultant equivalent stress may be beyond the yield-point of the material. For this reason, it is not surprising to the writer that pipe bends so often undergo permanent set when placed in service. This permanent set may annihilate the effect of cold-springing, allowing excessively high reactions to be set up on turbines, anchors, etc. For these reasons, in the future, it might be desirable to specify limits

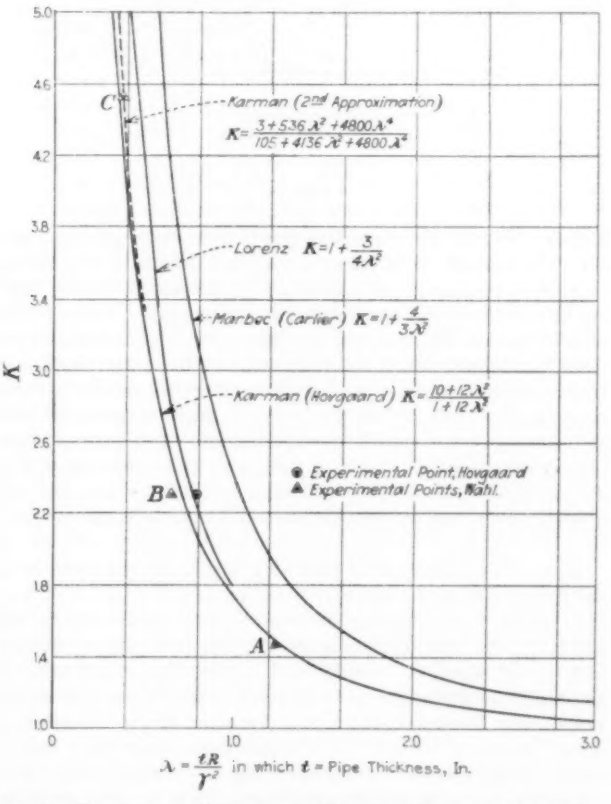

FIG. 37 FLEXIBILITY CONSTANT AS GIVEN BY VARIOUS INVESTIGATORS

(R = radius of pipe bend, in.; r = mean pipe radius, in.)

[14] *The Engineer* (London), Sept. 7, 1928.

to the permissible ellipticity produced in pipe bends during fabrication. At least this would tend to eliminate another uncertain factor from the problem.

On the whole, the writer believes that some such code as proposed by the author should replace the tables and formulas given in our present handbooks and catalogs. These ordinary formulas are obviously not rational, in the light of our recent knowledge of this subject. Whether the code proposed by the author is the best remains to be seen, but at least it is an improvement on those ordinarily used.

In the writer's opinion, the big question in designing pipe bends is whether the ends of the pipe can be considered fixed or

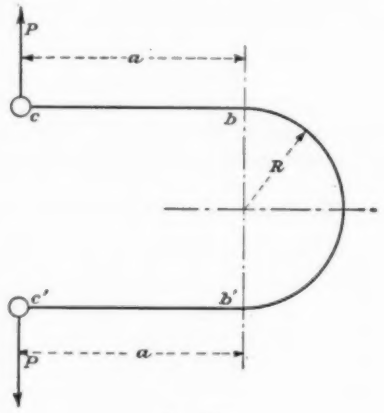

FIG. 38

hinged. On the answer to this question depends, in large measure, the amount of stress and reactions set up in the piping. In view of the indeterminate nature of the end conditions existing in most practical installations of pipe bends, it seems to the writer that the safest course to pursue would be to assume the worst conditions, which would usually be fixed-end conditions. In certain cases, however, such as those where unrestrained lateral movement of the pipe line is allowed, it might be permissible to assume hinged-end conditions in calculation. It is thus apparent that a certain amount of good judgment as to the proper conditions to assume must be exercised by the pipe-line designer when applying the various theoretical formulas to his problem.

KARL D. WOOD.[17] The following points do not seem to be clearly emphasized by the text of the paper.

1 Table 2, which compares several theoretical formulas for the factor K which expresses the relative flexibility of straight and curved pipes, is a unique and outstanding contribution to the American literature on this subject, since the work of neither Lorenz nor Marbec appears to have come to the attention of other American writers. While the table shows the Lorenz theory to be the most reasonable, Fig. 13 shows it to be supported by only one experimental point, while no data are given supporting the other theories. This indicates a very profitable direction for future research, since significant results should be obtainable at small expense.

2 The quantitative treatment of fixedness of ends of pipe lines, as shown in the last line of Fig. 14, appears to be also a novel and valuable idea. While the table attempts to verify values of both fixedness and flexibility factor K, and therefore verifies neither, it indicates that simple experiments may be conducted in the future which will check both factors by holding one of them constant at a time.

3 While Fig. 15 shows that current practice for quarter-bends with fixed ends allows 100 times as much expansion as the proposed well-verified theory indicates would produce a safe stress, this need not imply that such pipe bends have failed, but rather that such bends have been subjected to excessive working and therefore short life.

4 In the proposed Code of Design Practice, the typical study of shape efficiency is based on an assumed constant total length of pipe. An assumption of constant yearly cost of pipe would, however, probably be a more practical basis of comparison, and not much more difficult than the one used. Principle No. 3 in Part I which summarizes this study is nevertheless valid and important; namely, that the maximum length of pipe should work at the maximum safe stress; and with this principle as a guide, a meaningful result can be obtained.

In spite of these criticisms, however, the writer feels that engineers will recognize this paper to be one of the most valuable studies of pipe expansion ever published, and he believes that the Society would do well to consider the issuance of a code of pipe-expansion practice similar to its other codes in the light of the material presented in this paper.

AUTHOR'S CLOSURE

The following comments are made in the belief that a brief summary of the entire case, attempting to voice the consensus of opinion of all who took part in the discussion, will be more helpful than a detailed study of each of the discussions.

Part I—Fundamental Principles to Be Considered in Design. This stands approved.

Part II—Survey of Published Work. To those given should now be added the splendid discussions of this paper and the work mentioned by Professor Hovgaard and Mr. Carlier.

Part III—Theoretical Analysis. The fixed-end and partial-fixity-of-ends theory stands approved. The work of Hovgaard and of Wahl points to the Karman as the correct theory for the flexibility constant, and the work of Jenks to the nth approximation of this theory.

Part IV—Comparison of Theory With Experiment and With Current Practice. The tests of small solid models verify the mathematical theory without disturbance from such factors as the flattening effect and lack of complete end fixedness which always exists in practice. The next step, which has been partially carried out as noted in the discussion, is a series of tests to check the flexibility constant. The final step, which it is hoped interested parties everywhere will undertake, is the check on actual layouts as used in practice. It is felt that a thorough theoretical groundwork has been laid for these tests and that the main factors to be considered have been pointed out.

Part V—Proposed Code of Design Practice. For the simpler shapes given, the solution is so simple that there is no longer excuse for the empirical and guess methods in quite common use. For the more complicated shapes mathematical and graphical solutions are available.

The author feels that the design of piping to care for expansion is much nearer the standardized basis on which most other branches of design rest than ever before, and the author expresses his thanks to his collaborators and to those who have contributed so much in the discussion for their large part in the achievement.

Design and Proportions of Economizers and Air Preheaters

By HOSEA WEBSTER,[1] NEW YORK, N. Y.

Thirty years ago 200 lb. working pressure and 40 lb. of coal burned per square foot of grate surface were the maximum. Superheat had not come into use. Since that time there has been a rapid development or evolution in the design of steam-generating and fuel-burning equipment. Today the rate of evaporation per square foot of boiler heating surface and the rate of fuel burning per foot width of furnace have increased 1000 per cent, and 1400 lb. steam pressure and 800 deg. steam temperature have passed the experimental stage, with indications that both pressures and temperatures may go higher where conditions of service and of fuel cost warrant. Modern high pressures and temperatures and high rates of fuel combustion have not only required much greater care in the selection, fabrication, design, and construction of pressure parts and furnaces and fuel-burning equipment, but also an entire rearrangement and distribution of heat-absorbing equipment. The temperature of the gases leaving the stack is an approximate measure of the overall efficiency. Recovery of the heat contained or carried in the gases leaving the steam generator proper may be accomplished by an economizer or an air preheater or both. Economizers of vertical cast-iron tubes decidedly antedate the increase in working pressures which required the use of steel tubes, now mostly horizontal and of the return-bend type, and because of the greater susceptibility to interior corrosion, may be fed only by water practically oxygen free. The introduction of pulverized coal requiring preheated air for proper combustion has greatly extended the use of air preheaters, of which three types are in use: tubular, plate, and regenerative. While the additional efficiency of a generating equipment runs from 3 to in some cases 7 per cent with economizers, it runs from 5 to 10 and sometimes more where air preheaters are used. Service and operating conditions may warrant the use of either or both, each plant being an individual problem of station economics.

CONCURRENT with and contributing in no small degree to the marvelous industrial and power development in this country since the end of the World War have been the improvements in the design and efficiency of steam-generating equipment which have made possible the coincident advances in design, capacity, and efficiency of prime movers. These improvements have been in the furnace and fuel-burning equipment and in the design, fabrication, materials, and disposition of steam-generating and heat-absorption surfaces.

Thirty years ago most boilers were hand-fired, with a few natural-draft chain grates and overfeed stokers. With the introduction of the underfeed stoker with under-the-grate forced draft came an increase in the rate of fuel burning per square foot of grate surface. Then, as now, the limit to the steam-generating capacity of a boiler fed with good water was the limit to the amount of fuel which could be burned under it. Furnace performance was stated in pounds of fuel burned per hour per square foot of grate surface.

Furnace performance as to input and capacity when the fuel is liquid, gas, or pulverized coal is generally stated in B.t.u. per hour per cubic foot of the furnace volume required for complete combustion within the furnace.

Reduced to its lowest terms, the problem of steam-generator design is, how far does it pay to go by reducing the temperature of stack gases in utilizing the heat which can be developed in burning the fuel available for the work to be done or power to be developed.

Manifestly, then, the first step is to determine upon the design of the furnace and fuel-burning equipment which will get the best combustion results from the fuel available, having in mind of course the variations in the maximum, minimum, and average rates of demand for the output of the installation.

An input of $2^1/_2$ to 3 million B.t.u. per hour per foot width of furnace is about the limit for a hand-fired stationary boiler. Underfeed and chain-grate stokers with forced blast can maintain an input of 20 million B.t.u. per hour per foot width of furnace, while recent designs of double-ended pulverized-coal furnaces are being offered for as high as 35 million B.t.u. input per hour per foot width of furnace. At these higher rates there are serious or difficult problems of a physical, chemical, and mechanical nature, requiring particular care in design and construction.

The increase in the rate of fuel input, at first gradual, but of late more rapid, was at first accompanied up to a certain point by a corresponding increase in the area of boiler heating surface per foot width of furnace.

This advance in methods of fuel-burning equipment has decidedly complicated the design of the generating equipment, the problem being how far and in what direction it pays to go in investing in heat-absorbing equipment to reduce stack losses and gain higher consequent overall efficiency.

In the case of central-heating and power stations where fuel cost is a considerable part of the selling price of the product, the problem is naturally more complicated than in an isolated plant where fuel cost is too small a part of the selling price of the product to warrant the complications of equipment and the operation costs required for high overall plant efficiency.

A high ratio of power or equivalent B.t.u. output to B.t.u. equivalent of fuel input is predicated upon a reduction of the temperature of the gases leaving the steam generator by using them to heat the feedwater by an economizer or to heat the air required for combustion by means of an air heater, or by both working in series.

The necessity for reheating the exhaust from high-pressure turbines has brought out the convection reheater which, utilizing the furnace gases as they leave the boiler proper, really is a form of economizer in that it takes heat from the furnace gases which is utilized in the low-pressure turbine.

While in isolated plants, notably in New England textile mills where the power requirements were constant, economizers with cast-iron elements receiving water at or around 150 deg. from auxiliary-feed heaters have for years been in general use, the higher pressures and higher rates of steam generation have brought into use economizers made up of steel elements. Although prior to the adoption of pulverized coal they were coming into general use in central-power-station practice, the use of extracted steam in heating the feedwater up to near the temperature due to the pressure carried in the boiler in order to maintain

---

Contributed by the Power Division and presented at the Rochester Meeting, Rochester, N. Y., May 13 to 16, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

station heat balance has somewhat reduced their use, they still appear in many station designs.

Today the design and construction of an economizer is not as simple as it looks. Subject to extremes of temperature and to various destructive chemical reactions inside and outside, the surfaces and flow area for both gases and water must be so designed and disposed as to give a maximum of heat transfer with a minimum of first cost and of space requirement for the necessary heating surface. Resistance to the flow of water to the boiler and draft loss must be kept within reasonable limits, and proper provisions must be made against exterior and interior accumulations which tend to reduce heat transfer efficiencies.

There should be no joints in the surface exposed to the furnace gases.

Two distinct types of economizer are on the market: vertical tube and horizontal tube. The former is sometimes an integral part of the boiler, but usually independent, and is usually cross-baffled to give several passes of the gases over the heating surface, usually entering the top and leaving at the bottom, the tubes being expanded into a lower drum which receives the feedwater and into an upper drum from which the heated feedwater passes to the boiler.

Before high pressures required the use of steel tubes, all economizers were made up of vertical cast-iron tubes pressed at each end into cast-iron headers. Mechanical scrapers keep the exterior surfaces free from soot.

Because it takes up less space there developed a demand for a horizontal steel-tube economizer, of which the return-bend type is coming into more general use. Disposed in horizontal rows one row above the other, the flanged ends of the tubes in each row are joined at one end to a tube above and at the other end to a tube below by a flanged return bend, making a male and female gasketed joint.

The topmost row of tubes is connected at one end to a forged-steel outlet header as is the lowermost row to a forged-steel inlet header. The tubes are carried at each end by a supporting plate which serves as an end casing for the economizer. The tubes pass the supporting plate by a gas-tight joint so that the return bends have their joints outside the gas passage and can be readily examined with the economizer in service.

Because of the consequent higher rate of heat transfer, economizers should operate on the counterflow principle, with gases entering at the top and feedwater entering the bottom and flowing upward.

An upward flow of gases with a downflow of water is apt to cause an annoying and possibly destructive water hammer and should be avoided.

To avoid external corrosion the area of heating surfaces and temperature of feed must be so proportioned that at any rate of operation the temperature of the tubes will be above the dewpoint of the gases, as any accumulation of moisture on the exterior of the tubes quickly absorbs any sulphurous gas coming from the fuel.

To avoid interior corrosion the feedwater must be kept free or practically free from air or carbonic-acid gas. The oxygen content of the water entering the economizer or boiler should be kept below the equivalent of 0.05 cc. per liter. Several deaerators and feedwater heaters are on the market which keep the oxygen content down to or below this point.

One advantage of the horizontal-tube return-bend type of economizer is that if corrosion does occur it is localized and requires replacement of only a small part of the surface.

Steaming economizers are in successful and satisfactory use. Steam is formed at high rates of evaporation in the boiler, with consequent high temperatures of outgoing gases.

Ordinarily an economizer should be so proportioned with respect to the surface of the boiler that the outgoing feedwater will be at least 50 deg. below the temperature due to the boiler pressure, but if conditions of station heat balance require multistage bleeding with feed temperature approaching that of the boiler water, the steaming economizer is fully justified and several are in use.

While not absolutely so, the temperature of the stack gases is indicative of the overall efficiency of the unit.

For the proper combustion of pulverized coal the requirement of moderately heated primary air and higher temperature secondary air has led to the use of air preheaters utilizing the heat in the flue gases and cooling them prior to their entrance to the stack. Experience has shown that their use with liquid and gaseous fuel and also with stokers in most cases pays a profitable return upon their first cost.

While much more are used than ever before, air heaters are by no means a novelty, as the records show their use abroad over a hundred years ago in metallurgical furnaces.

All the early English patents covering air preheaters, of which over fifty had been issued by 1839, based their claims on smoke reduction, and the use of preheated air to get better plant-combustion efficiency does not appear to have been considered until about 1870. The first installation in this country was in a New England plant in 1878. In marine service preheated air has been in use for years, with forced or induced draft installations, but it required the modern increases in fuel costs, demand for high efficiencies, and high rates of steam output to make their installation seem worth while in stationary boilers.

The ideal air heater gives a maximum heat-transfer rate with minimum draft loss, minimum leakage, minimum space requirements, and ease of access for cleaning and repair.

The first two factors are intimately related, and the forms of gas and air channels have a bearing on the transfer rate, which is primarily a function of gas and air velocity, which in turn governs the draft loss and air-flow resistance or friction.

As in the case of economizers, consideration must be given in their design to cost of power required to overcome the frictional resistance.

There are so many variable factors involved that no universal rule or formula can be devised for the proportions of economizers and air heaters.

Each case is a complicated problem requiring individual solution to determine how far and in what direction it will best pay to go in reducing the temperature of stack gases with an adopted method of burning the fuel available.

There are three distinctive types of air heaters: tubular, plate, and regenerative. All have their advocates, and often space requirements or limitations govern the type selected.

The tubular and plate heaters are usually vertical, utilizing the countercurrent principle in gas- and air-flow direction.

Vertical tubular air heaters are made up of vertical steel tubes expanded at their upper and lower ends to generally horizontal plates. The fit at one end of the tubes is usually just loose enough to permit any expansion and contraction which may occur as a result of uneven distribution of gases or air over the surface.

The gases entering the bottom flow inside the tubes to the top. The tubes are enclosed in a casing which serves as the air flue, down which and over the outside of the tubes the air passes.

There are several forms of plate air heaters which fundamentally consist of vertical parallel plates spaced from $1/2$ to 1 in. apart and so joined at their vertical edges that the air passages alternate with the gas passages. The air and gas inlets and outlets are so disposed as to give countercurrent flow. They usually require less height than the tubular type of equal capacity. In some designs the plate ends are joined by welding; in others, by gasketed joints.

As with tubular and plate heaters there are several designs of the regenerative type on the market. Usually they are made up of metal elements so disposed that they are first heated by the flue gases and then give up the heat to a succeeding flow of air. In some designs the elements pass alternately into the gas and air passages; in others, the elements are stationary and are alternately bathed in flue gas and in air.

In design and material, provision must be made to withstand the temperature extremes of entering hot gases and relatively cold air and consequent expansion and contraction, as well as for cleaning the surfaces over which furnace gases pass, with oftentimes resulting soot and dust deposits which rapidly reduce the heat-transfer rate. As cooling the furnace gases below the dewpoint of some of their chemical constituents results in rapid corrosion of the tubes or plates, care must be used to avoid too much surface.

While the additive efficiency characteristic of an assumed economizer can be exactly calculated, such is not the case with an air heater, as there are two factors involved—first, the saving due to the heat brought back to the furnace; second, that due to the resulting increased furnace temperature, with consequent higher combustion efficiency.

Opinions differ as to the amount of increase in furnace temperature resulting from increasing incoming-air temperature, but it is probably from one-fifth to one-third of a degree for each degree increase in entering air. It is probable that some fuel characteristics enter into the problem.

With most bituminous or semi-bituminous coals there is a temperature at which they will begin to soften. This characteristic limits the temperature of the primary air for pulverized-coal equipment and of the air passing through the fresh coal bed of both chain-grate and underfeed stokers where the temperature is high enough to cause the coal to mat and to cut off or greatly reduce the air flow. Another limitation to air temperature with stokers is the necessity of avoiding overheating the grates and other structural details.

In the case of stokers, preheating the air unquestionably results in better and quicker ignition, shorter flame, and a marked decrease in the loss from unconsumed carbon in the ash and higher possible rates of fuel input.

Inasmuch as they utilize furnace heat which has not been used in generating steam, convection reheaters which resuperheat the exhaust steam from high-pressure turbines on the way to the low-pressure turbine throttle are really a form of economizer. As modern practice calls for reheating the steam to 700 to 800 deg., the gases coming from the boiler must have the high temperature characteristic of high rates of evaporation. The temperature of the gases leaving the reheater depends upon the temperature and B.t.u. content of the incoming steam. Usually the outgoing-gas temperature warrants the use of both a relatively small economizer and an air heater of the highest efficiency.

A number of designs are in successful use, all tubular in construction and varying greatly in the distribution of surfaces and gas- and steam-flow areas which depend primarily upon the temperature and pressure of the incoming steam and upon the temperature of the outgoing steam.

The flow area of the tubes and headers must always be large enough to avoid any material pressure drop of the steam passing from the inlet to the outlet.

Rates of heat transfer with economizers and air heaters vary, of course, with the variation in the output of the equipment. In the earlier days of cast-iron economizers, 2 B.t.u. per square foot per degree of temperature difference was the average. The rate of transfer varies with the velocity flow of the fluids over the heating surface, which in turn is accompanied with varying frictional resistance, to overcome which consumes power.

TABLE 1 SERVICE CONDITIONS AND PERFORMANCE CHARACTERISTICS OF PRESENT-DAY TYPICAL COMBINATIONS OF BOILER, ECONOMIZER, AND AIR HEATER PER FOOT WIDTH OF FURNACE

* Steaming economizer.
† Bituminous coal, cols. 1 to 13; oil, col. 14.

Proper proportions of velocities and flow areas and their relations to fuel cost, load factors, and first cost are factors which enter into the design of economizers and air heaters and steam reheaters.

Table 1 gives a comparative analysis of a number of typical combinations based upon their performance per foot width of furnace. It will be noted that the additive efficiencies due to the air heater considerably exceed those characteristic of economizers.

Some of the lower efficiencies of stoker-fired units are due to the assumption of a progressively increasing loss due to unconsumed carbon in the ash, which with more recent designs using preheated air is not warranted. Measurement of unconsumed carbon in the ash is not so easy to determine with pulverized coal and has been assumed to be relatively small. In making up the table, no account has been taken of the cost from car to burning equipment.

In conclusion it may be said that the improvements in design of fuel-burning equipment have resulted in an increase of rates of combustion which is bringing about an evolution in the design of the heat-absorbing equipment, which is progressing toward a standardization of details and proportions and away from more expensive and, to an extent, experimental installations.

While higher pressures, higher temperatures, and greatly increased rates of fuel input have not required any material changes in the fundamental design of the steam-generating and heat-absorbing equipment, they have required much advance in refinement of details of materials and construction to durably withstand the sudden and extreme changes in temperature and pressures characteristic of modern operating and service conditions.

For the isolated or industrial plant an equipment consisting of a properly proportioned combination of steam-generating or boiler-heating surface with an air heater, because of its simplicity and low cost of operation and upkeep, will pay a good return upon the first cost.

For central stations where the factors involved are more numerous and complicated, economizers or air heaters or both have become necessary, primarily because of the relation of fuel cost to selling price of the product.

Attention is almost daily called to the fact that while the last ten or fifteen years have witnessed an increase in the cost of most everything else, the cost of electric power has remained almost without change, and in many cases has been reduced. To this condition the improvements in design and construction of the steam-generating equipment and its accessories have contributed in no small degree.

FSP-51-54

Progress in Steam-Power Engineering

Contributed by the Power Division

Executive Committee: Vern E. Alden, *Chairman*, W. F. Ryan, *Secretary*, John A. Hunter, F. M. Gibson, and V. M. Frost

DURING the past year we have seen a great deal of intensive work in the consolidation of gains incident to past progress and the raising of the average standard of steam-station design and operation throughout the country, although there have been no strikingly new developments.

The developments, which during the last 15 years have made it possible to reduce by 40 per cent the fuel consumption per kilowatt-hour in steam-electric generating stations and to effect a reduction of more than 50 per cent in fuel consumption for power generated by the mercury-vapor process, are ample evidence of the intensive work done by hundreds of designing and operating engineers. One of the most important factors which has contributed to rapid progress is the free exchange of ideas and the pooling of operating experience through the medium of the A.S.M.E. and the Prime Movers Committee of the National Electric Light Association. Steps have been taken during the last two years by the A.S.M.E. Power Division to provide for the freer exchange of ideas between those of our members who are associated with the industries. It should be a source of satisfaction to the many designing and operating engineers, who by their work have contributed to the progress in steam-power engineering, to know that they have had a substantial part in bringing about the present era of prosperity in this country, resulting in no small measure from the abundant supply of cheap power with which the efforts of each man in industry have been supplemented. It should be no less a source of satisfaction that the rapid progress has been so largely the result of full cooperation and the pooling of ideas and operating experience, for where else than in the United States could this have happened?

Some Major Objectives Attained

It is interesting to take stock of some of the major objectives actually attained:

1 The types of fuel preparation and burning equipment which are available permit the efficient burning of coal varying in grade from lignite to anthracite.

2 Fuel-preparation and burning equipment is available which is sufficiently flexible so that coal of widely varying grades may be burned in connection with a single installation.

3 Fuel-burning equipment, boilers, and boiler accessories are available which permit the generation in a single boiler unit of the steam required for a 75,000-kw. turbine.

4 Single-cylinder turbines of 75,000-kw. capacity, tandem-compound turbines of 160,000-kw. capacity, and cross-compound turbines of from 200,000-kw. to 300,000-kw. capacity are available.

5 Equipment is available for operation at steam pressures up to 1400 lb. per sq. in. gage and steam temperatures up to 750 deg. fahr. (There is considerable evidence to indicate satisfactory operation at even higher temperatures.)

6 Equipment is available for the reheating of steam withdrawn from the lower stages of the turbine, using either the heat from flue gases or the latent heat from high-pressure steam.

7 There is available equipment for heating feedwater by means of the regenerative cycle, using from three to five stages of heating.

8 Furnace water-wall construction is available which eliminates to a great extent the use of refractories in the portions of the furnace walls, which are subjected to the highest temperatures.

9 Condensing equipment is available which will maintain high vacuum with low investment and operating costs.

10 Economizers and air heaters are available by means of which the losses in the flue gases are reduced to very low values; and the investment and maintenance incident to the use of this equipment are reasonable.

11 There is available commercial equipment for operation on the mercury-vapor–steam cycle, each unit in the boiler house being capable of developing up to 20,000 kw. capacity.

12 There is available combustion-control equipment which will maintain day in and day out in the boiler house, operating efficiencies closely approximating test efficiencies.

13 For the average power station it has been possible to reduce the make-up water to approximately 1 per cent, which may be easily evaporated with an inappreciable loss due to the degrading of heat. For boiler plants requiring a high percentage of make-up, equipment is available which makes it possible to maintain conditions of operation and a degree of reliability and availability of boiler units closely approximating that for boilers operating on distilled water.

14 The coal- and ash-handling equipment now available make very low labor costs obtainable.

It is possible, assuming favorable conditions, to produce power by using the straight steam cycle with 12,500 B.t.u. per kw-hr. of net send-out, and, assuming the same favorable conditions, to produce power with from 11,000 to 10,000 B.t.u. per kw-hr. of net send-out by using the mercury-vapor–steam cycle of generation.

We have available today all of the equipment and the knowledge required for the assembly of this equipment and for its operation to permit us to build highly efficient generating stations, varying in size from the superpower station of 1,000,000-kw. capacity to the industrial plant of 1000-kw. capacity.

Problems Suggested for Study

It is interesting to speculate as to the possibility of future developments in research which will lead to the reduction in fuel consumption per unit of output. It will, however, be more profitable and certainly more effective in the reduction of the costs for power available to our generation, if we concentrate on a study of the best use of the knowledge and the equipment which are now available to us. That we may make further appreciable reductions in the total cost of power and steam, an intensive study of certain problems is urged. The responsibility for this study lies with the engineers who design the generating stations and boiler plants, the engineers who design the equipment, and the engineers who operate these plants. The responsibility for making major decisions rests with the executives of the operating companies, but the responsibility for proper guidance of the executives lies with the engineers. The problems suggested for study are:

Reliability. The need for steam-station equipment which will be available for operation during the largest possible percentage of the hours in the year transcends all other needs. Definite progress has been made in supplying this need. The almost universal use of the closed system of ventilation for generators has re-

duced the outage hours by at least one-third. The use of water-cooled walls for boiler furnaces has, by the elimination to a large extent of refractories and the reduction in the maximum rate of heat absorption by surface which "sees" the fire, reduced the outage time for boiler units by at least an equal amount. Some progress has been made in reducing the outage time for turbines, but there is still room for further improvement. It is mainly to the turbine designer and the engineer carrying on research in blade structures and metallurgy that we must look for further help in improving the reliability of the turbine.

The improvement of design details in connection with major equipment; the careful selection of auxiliary equipment; the division of the auxiliaries for each large major piece of equipment into two or more units; the careful design of piping, giving full weight to the operating man's viewpoint; and the carrying through of continuous and adequate inspections which will permit the scheduling of much of the maintenance and repair work for convenient periods when equipment is not needed for operation; these and other related work will go far toward reducing the time during which equipment is not available for service.

Investment. The fact that the fixed charges allocated to each kilowatt-hour on an average exceed the fuel costs by at least 50 per cent emphasizes the possibilities of a reduction in the total cost of power through a reduction in the investment. During the last three years the emphasis has been more largely placed on the reduction of investment, and worthwhile results have been obtained.

Reserve Capacity and the Date of Starting New Power-Station Extensions. On an average, the sum of the fixed charges and maintenance on reserve capacity constitute at least 10 per cent of the total cost of power on the station bus bars, and their combined value is equal to 25 per cent of the fuel cost. The importance of reducing the investment in reserve capacity to the lowest figure consistent with the maintenance of reliable service is self-evident.

The accurate prediction of the growth of power loads so as to defer extensions as long as possible and the advance planning of work which will make high-speed construction schedules possible will permit the reduction in fixed charges on unproductive investments.

Size of Units and Stations. No more important problem confronts the power-station engineer than the choice of size of units to be used in the turbine room and boiler house. Choice of units which are either too large or too small will increase the total cost of power on the station bus bars. The decision as to the ultimate size of a given station is one which can seldom be made with exactness at the time that the initial installation is made. This question is directly related to the geographical distribution of the load and the design of the transmission system.

Interchangeability of Equipment and Production in Development Costs. There is probably no single factor which will contribute more to the simplification of operation and maintenance, and the reduction of the fixed charges allocated to each kilowatt-hour generated, than the use, in a station, of main generating units having interchangeable parts. The argument for interchangeability of parts holds with almost equal force for other equipment in the station, and particularly for the important auxiliaries, such as boiler feed pumps, condensate pumps, and circulating pumps. In order to obtain interchangeability, it is justifiable in most cases to make the decision as to size of units on the basis of operating conditions and the system load as they will be when the station is half completed, rather than on the basis of conditions during the first year of operation.

A high degree of interchangeability of equipment in a given station and also interchangeability of equipment in different stations operated by the same company will tend toward reduced investments through reduced development and reduced manufacturing costs.

Quality of Fuel Burned. In many cases two or more kinds of fuel are available. Careful studies must be made to determine the wisdom of designing the fuel-preparation and burning equipment for burning one of these kinds of fuel or of making provision for burning several different kinds of fuel. The continuity of supply and the probable trend of costs of fuel must be considered.

Location. The choice of location for a new power station bears definitely on the cost of power delivered to the user, as it affects the cost of construction, the cost of fuel, the cost of operating labor, and the investment in the transmission system.

Simplification and Ease of Operation. Much can be done in the way of simplifying operation by uniformity of design throughout a given station and by the elimination of details which can readily be dispensed with. The designing engineer should, in making each decision, give due weight to the viewpoint of the man who must operate the station. The designing engineer should in every case transmit to the operating organization a clear-cut statement as to the provisions which he has made for various operating contingencies and not depend upon the art of mind-reading, which is not now well developed among operating engineers.

There is a crying need in connection with our newer stations for better operation. The concentration of responsibility for operation in the hands of fewer men, the vastly increased value of the avoidable losses under the control of each operating man, and the unavoidable complexity of the equipment which we must use to obtain a fuel economy of 15,000 B.t.u. per kw-hr., or lower, all justify and make imperative a high degree of intelligence in the men who operate our stations. Intelligence is not enough, however. These men should be given every opportunity to acquaint themselves with the details of construction and the operating principles which underlie each piece of equipment. One of the most important opportunities of which we are now in large measure failing to avail ourselves is that of making provision so that to a greater extent the results of the work which is being done by the N.E.L.A. Prime Movers Committee and the A.S.M.E. Power Division shall filter down to these men who are actually operating the stations. Their help is needed if power costs are to be further reduced.

These problems are intimately interrelated. They form the basis for an intelligent attack on any power problem whether it involves the construction and operation of a 1,000,000-kw. superpower station, or a boiler house for an industrial plant. An intimate understanding of the fundamental principles of steam-station engineering and a knowledge of the work done by other engineers, for which there is no substitute, is presupposed. Clear thinking, which will enable the engineer to pick the solution called for by a particular set of conditions, and a full realization that the same type of solution and the same kind of results are not to be expected in connection with a 1000-kw. station and a 500,000-kw. station, are the necessary equipment of the engineers who are to effect further reductions in power costs.

It is questionable if any branch of engineering presents a more interesting problem, or one which is more important to our whole country, than the production of an abundant supply of reliable power at the lowest cost. The splendid results already obtained make each additional reduction in cost of power increasingly difficult. Difficulties have, however, always served as the incentive and not the obstacle to engineering work.

VERN E. ALDEN, *Chairman.*

Progress in Hydraulics

Contributed by the Hydraulic Division

Executive Committee: Ely C. Hutchinson, *Chairman*, H. L. Doolittle, *Secretary*, R. L. Thomas, W. M. White, and L. F. Moody

THE progress report of the Hydraulic Division for 1927, submitted by Mr. Ely C. Hutchinson, was a comprehensive survey of the hydraulic field. Since the preparation of that report there have been no outstanding new developments or trends in machinery or methods, and few changes in practice. The intervening period has, however, witnessed intensive and successful effort along several of the lines of development noted last year, and particularly an increased striving to approach the goal of perfection in economy of design and operation. Hence this year's report must be in large part a follow-up or bringing up to date of last year's report.

This condition is to be expected, as in the nature of things progress in hydraulics is slow as compared with that in some other branches of engineering, as, for example, steam-power generation. Hydraulic machinery of many types has reached an advanced stage of development. Theoretical maximum efficiencies have already been closely approached in the turbine field, recent reaction-turbine tests having shown efficiencies up to 94 per cent, although there is a larger margin for improvement in part-gate turbine efficiencies and in pumping equipment. Also changes must come rather slowly, as several or often many years are spent in the preliminary study, design, and construction of hydraulic works.

It seems to be a fact that there has been a slowing down of water-power development in the United States, although the same cannot be said of Canada, which in relation to demand is more richly endowed with low-cost water-power sites which do not have to compete with cheap local fuel supplies. The past year is notable for the important hydraulic-power plants which were put into operation, but these have been in the making for several years and are more or less familiar to hydraulic engineers. In spite of unusually favorable financial conditions, comparatively few important projects have been undertaken recently in the United States. This slowing down has been ascribed to two causes or groups of causes: first, political agitation and governmental interference or indecision, extraordinary taxation, and the withdrawal of some of our most important rivers and sites from the provisions of the Federal Water Power Act; and second, the economic condition brought about by the decreased cost of steam-generated power and the previous development of the cheapest and most accessible water-power sites. Also it is believed by some that the falling off is temporary, as the industry has always been subject to periodic fluctuations.

Economics of Hydraulic Power

The outstanding recent trend in the hydraulic-power field is economic rather than mechanical; that is, the best efforts of power engineers, manufacturers of equipment, and users thereof are being devoted to lowering the cost of water-power development, improving the economy thereof, and working out the best economic use of water power in coordination with steam power. With the growth of interconnection, the all-hydroelectric generating system is becoming a thing of the past in the United States. The combination of hydro and steam power makes possible the economic justification of many otherwise impracticable water-power projects. Formerly it was possible and customary to justify a hydro development, particularly a run-of-river project, in comparison with steam power by evaluating the operating replacement cost of the equivalent steam-generated energy, or often the saving in fuel cost alone. This is no longer possible on account of the great advances in the economy of generation at steam-electric plants. As the efficiency of hydraulic-power generation has already approached the theoretical maximum, it is not possible to meet steam competition by improvement in efficiency alone, and recourse must be had to lowering the investment cost through simplification of layout, elimination of nonessentials, and improvement in design; to the extensive overdevelopment of streams with respect to minimum dependable flow and continuous capacity; to the use of additional steam units to carry load increments until such time as the load has grown sufficiently to absorb the output of the next hydroelectric step; and to realizing, utilizing, and capitalizing the advantages of hydro other than its energy-replacement value. Among these may be mentioned the capacity value or peak service of even a small amount of hydro energy, as from a variable-flow stream plant during minimum flow, when properly applied; the mechanical ruggedness and quick-starting properties of hydraulic units; diversity of maintenance work and station trouble; improved reliability and distribution economy obtained by a strategic arrangement of points of supply from the independent hydro and steam sources; stability of annual cost; and sometimes the location value of hydro plants as, for example, a small local plant at the market end of a long transmission line the economy of which depends on the maintenance of a high line load factor.

Another former practice which is being and should be discarded is the requirement that the development of a water-power project must effect a handsome saving or profit as compared with an all-steam supply. It is encouraging to note that in the case of a recent important project the backers of the development stated at once that in dollars and cents the project might not effect any immediate saving, but pointed out that if the costs of hydro power and steam power are approximately the same, the desirability of conserving our fuel resources should throw the balance in favor of hydro power.

A noteworthy current activity is the revamping and in some cases the complete reconstruction of old hydraulic plants.

A phase of the hydraulic-power business which is receiving considerable thought is practice in drawing up contracts and purchasing equipment. As noted last year, the manufacturers have felt that, owing to competition and perhaps some slowing down of business, prices have been very low and have left little margin for experimental work. On the other hand, the users of equipment have pointed out the keen competition with steam power and the need for rock-bottom prices. A solution that has been offered is an improved form of bonus contract with less stress on high guaranteed efficiencies and a reward for efficiency in excess of the guarantee. An interesting example of such an arrangement which worked out satisfactorily to both parties is the recent replacement of the buckets on the original Big Creek impulse wheels of the Southern California Edison Company. The power company agreed to pay the manufacturer a certain amount for the new buckets and a bonus of so much per kilowatt for any increase in output obtained with the new buckets over

that obtained under like conditions with the old buckets. A considerable increase in efficiency and capacity was obtained. The manufacturer immediately devoted his bonus to further experimental work, as a result of which still more efficient buckets were developed.

There is an encouraging tendency in the West to effect cooperation between irrigation districts and power companies. In several cases the utility company owns and operates the power plant built in conjunction with the irrigation dam, paying the district a stipulated charge for the released water.

There is no cause for pessimism as to the future of water-power development. Necessity is a good stimulant. The working out of the various problems mentioned, together with the undoubted popularity of water power, should insure the development of large additional amounts.

Dams

The failure of the St. Francis dam in California has received much publicity. The causes have been thoroughly investigated and are well understood, but cannot be discussed here. The failure has undoubtedly shaken the confidence of the public in the stability of existing dams, although the fault was in the foundation rather than in the dam itself. The lesson seems to be that the work of municipalities should be subjected to supervision just as much as privately owned dams. It is to be hoped that in the effort to remedy the situation and restore public confidence in the safety of dams, extreme legislation will not be passed unnecessarily increasing the size and cost of the structures.

The completion of the principal tests on the Stevenson Creek Arch Dam and the publication of data and findings in the Proceedings of the A.S.C.E., May, 1928, Part 3, under the auspices of the Engineering Foundation, are an important achievement and have done much to put the design of thin-section, and particularly arched, concrete dams on a scientific basis. As described in the test report, tests made by Professor Beggs with a celluloid model one-fortieth of actual size indicated the probability that deflections in an arch dam can be predicted accurately from tests on models. Since the printing of that report, tests have been conducted with a concrete model at Boulder, Colo., which confirm the previous important findings regarding prediction of deflections in full-sized arch dams.

As a result of research work and experience there is increasing confidence in less-than-gravity-section types of dams. Several multiple-arch dams have recently been constructed. The Coolidge dam of the U. S. Indian Service on the Gila River, Ariz., recently completed, is a unique multiple-dome type.

There is an increasing use of rock-fill dams with thin reinforced-concrete faces.

Much study has been given to the design of dam aprons to prevent erosion of the foundation at the toe. The Conowingo and Norwood dams are notable examples of apron design based on experimental research.

There is an increased tendency to install permanent and substantial crest gates on dams rather than renewable flashboards. Clear-crest dams have become the exception rather than the rule. There still remains considerable room for improvement in the design of deep-crest gates and their operating mechanism to insure simple and reliable operation and low maintenance as well as investment cost. Recent floods in several sections of the country, particularly in California, with runoffs in many cases twice as great as any previously recorded, have shown the necessity for more liberal design and substantial construction of crest gates.

In 1928 two especially large roller crest gates or rolling dams, each 115 ft. long and 18 ft. high, were put into operation at the Bellows Falls plant of the New England Power Company on the Connecticut River.

As a means of rapidly draining reservoirs in times of emergency, an alternative for additional crest gates is the installation of discharge valves. There is an increasing demand for an inexpensive valve of large capacity. Such a valve need not be efficient. It will be called upon to function perhaps only once in several years, but at such a time must be capable of discharging a maximum quantity of water in a minimum time.

A feature of masonry dams with respect to which there is considerable difference in practice is the provision of inspection galleries, particularly for lower-head dams. Standardization in this respect may not be desirable, but there appears to be room for the dissemination of information and the establishment of principles of good practice.

An important subject of current investigation is the proper proportioning of concrete and methods of mixing and pouring, especially in northern climates. Attention has been called to a number of dams recently repaired which are less than ten years old.

Important Hydraulic-Power Developments

An unusual number of hydroelectric plants which are noteworthy either for size or special features or both have been put into successful commercial operation recently. Among these may be mentioned the Conowingo development on the Susquehanna River, containing the largest turbines in physical size yet built on this continent; the Louisville development on the Ohio River, the largest semi-automatic plant in operation and containing the largest propeller-type wheels in physical size that have been installed in the United States; the Norwood development on the Yadkin River, with several unique features; the Bucks Creek plant on the Feather River, with the highest head yet developed in America (2562 ft.); the Big Creek 2A plant, containing impulse units of record capacity (56,000 hp.); the Lake Chelan development in the State of Washington; the Upper Tallassee development in Alabama, the Bellows Falls development on the Connecticut River; the Rocky River development in Connecticut, the first important plant in America to use in large part pumped water; the small automatic plant built on "stilts" over the Kentucky River at Dam No. 7; the Glines Canyon plant in the State of Washington, the Spaulding No. 3 plant in California, and the Alouette plant in British Columbia, all notable automatic plants; and the extension of the Great Falls plant, Manitoba, containing propeller-type wheels notable for size and high head (56 ft.). Data regarding these installations may be found in the reports of the Hydraulic Power Committee of the National Electric Light Association on "Bibliography of Hydraulic Subjects and Manufacturers Statements" for 1927 and 1928. Special features will be mentioned hereinafter.

Important projects now under construction are the Paugan development on the Gatineau River, the Alcoa development (Chute-à-Caron) on the Saguenay River, and the Back River development in Canada; Jordan Dam (Lock 18) on the Coosa River; the Saluda, Waterville, and Oxford developments in the Carolinas; the Lower Tallassee development in Alabama; and the Fifteen Mile Falls development on the Connecticut River.

Turbines and Accessories

The propeller-type turbine continues to hold a prominent place in hydro-plant equipment. The completion of the Great Falls, Manitoba, plant, with a total installation of six high-speed wheels each rated at 28,000 hp. at 56 ft., after a lengthy experience with the first units, is worthy of note.

Probably the outstanding current development in the turbine field is the adjustable-blade runner, which with manual operation,

requiring the shutting down of the unit for adjustment, makes possible increased output under reduced head during flood flows, when efficiency is not a consideration. The largest units of this type in America will be the wheels rated at 8800 hp. at 26 ft. and 85.7 r.p.m. in the Back River plant in Canada, now under construction.

When the turbine-blade angle is changed automatically, high efficiency is obtained at part load, thus overcoming the principal disadvantage of the propeller-type turbine. The first installation of this type in America will be at the Devils River plant of the Central Power & Light Company in Texas, with a wheel rating of 1900 hp. at 33 ft. and 277 r.p.m. Based on laboratory model tests, the manufacturers expect the wheels to exceed 80 per cent efficiency from 575 to 2300 hp., and 90 per cent from 950 to 1575 hp.

In reviewing the year's progress, special mention must be made of advance in the design of impulse wheels, which is of particular importance in the West. Official tests of the Bucks Creek wheels showed efficiencies of 85 per cent or better over a considerable range.

The increase in cooperation between power companies and irrigation projects has emphasized the importance in such cases of obtaining high efficiencies over a wide range in head. The Melones plant of the Pacific Gas & Electric Company is a notable accomplishment in this respect.

Governors are being equipped with new control devices to adapt them for automatic or semi-automatic plant operation. The electric governor drive is being used in an increasing proportion of new installations.

Many turbines have recently been equipped with automatic air admission valves for increasing part-gate efficiencies and particularly for facilitating operation of the direct-connected generators as synchronous condensers for power-factor correction and voltage regulation.

The effort to reduce the cost of low-head turbines has led to the construction of turbine parts such as distributer rings, stay vanes, and head covers of welded plate and structural steel.

Repair of pitted turbine buckets by electric welding has become standard practice. Efforts to find a cheap substitute such as type metal, which will serve as a cheaply applied but durable filler, have as yet been unsuccessful.

Several additional rubber guide bearings have been installed on large turbine shafts, and those previously installed continue to give excellent service with negligible wear.

There is an increasing use of large butterfly valves instead of head gates in turbine intakes. The principal advantage is the tight seal which can be obtained, with consequent reduction in leakage during shutdown. The largest valves of this type, with a diameter of 27 ft., are in operation at Conowingo. These valves are sealed with rubber rings or tubes $\frac{1}{2}$ in. thick and $3\frac{1}{2}$ in. outside diameter imbedded in the casing around the valve disk and held in place by steel keepers. These seal rings have exceeded all expectations. A test with normal head pressure on the gate and a hydraulic pressure of 80 lb. per sq. in. applied to the sealing tube showed a leakage of less than $\frac{1}{2}$ cu. ft. per sec. A test on a $12\frac{1}{2}$-ft. butterfly valve at Rochester, N. Y., on a unit operating at a head of 130 ft., showed a leakage of less than $2\frac{1}{2}$ gal. per min. Another test on a 102-in. valve under a pressure of 100 lb. per sq. in. showed a leakage of 4.1 gal. per min.

Cylinder gates outside of the wicket gates have been used in at least two recent turbine installations to reduce leakage to a minimum.

Other Features of Hydroelectric-Plant Design, Construction, and Operation

There has been a notable development and use of equipment for the semi-automatic or remote control of individual generating units within a station, as at Louisville, and for the automatic operation of a plant as a whole, particularly when it is suitably situated with reference to a larger master station. Automatic operation facilitates the development of isolated water-power sites and serves in some measure to meet the decreasing cost of steam power. Particular interest centers on plants in which there is no governing equipment. Important automatic plants which have been put into operation recently have already been mentioned.

The overlapping of the heads of plants in series on the same stream is becoming more common. Under this arrangement headwater at the lower plant is normally high enough to cause backwater in the tailrace of the upper plant.

As a means of reducing the first cost, the so-called outdoor or semi-outdoor type of station has recently been adopted in several instances. The most notable example is the Norwood plant, with a close-fitting individual removable plate-steel housing for each generator. Another interesting feature of the Norwood plant is the improvement of overall plant efficiency by the installation of two different types of Francis unit. There are two relatively high-speed units and one with lower speed and capacity but higher part-gate efficiencies for load and frequency regulation.

In recent years much study has been given by many companies to the working out and following up of schedules or rules for the most economical distribution of load among units and stations. In the last analysis all of these schemes depended on the human element in that the operator was relied upon to carry out the proper loading. Recently a method has been developed for the automatic control of the loading of generating units and plants. The device, which in effect is a mechanical operator, is at the time of writing being installed at the Norwood plant. The equipment consists of instruments for the control, through the operation of the synchronizing motor on the turbine governor, of the load on a unit, while the governor continues to care for sudden load changes in the usual manner. In effect the device does what a skilled operator would do after a governor action in "touching up" the synchronizing motors on the units affected in order to restore or maintain the proper load. The system can be applied to distribution of load between stations, hydro or steam, as well as among individual units in the same station.

Another automatic-control device which functions through the governor-synchronizing motor is a frequency control. This seems to have been worked out independently in somewhat different form in two or three places.

Last year's report pointed out that the troublesome problem of penstocks for high-head plants has apparently been solved. It is interesting to note that the three plants in America with the highest heads—Balch, Bucks Creek, and Big Creek 2A, with heads of 2381, 2562, and 2419 ft., respectively—have used band-reinforced steel pipe, consisting of a welded steel core around which are shrunk seamless steel bands. With these bands the thickness of the lap-welded core can be kept within limits which insure good welds.

A need has been felt for an improved design of intake structure and gate mechanism for the control of a flow tunnel leading from the bottom of a deep reservoir. Vibration trouble has been experienced with two different types of regulating gate at part-gate openings.

Much attention is being given to power-house-crane design, long-distance water-level gages, continuous or intermittent water measurement by the use of venturi sections, etc., the removal of trash on racks by mechanical rakes, the prevention of ice accumulation on racks and turbine parts by electric heating, electric means of keeping fish from entering intakes, and mechanical fish elevators.

Pumping Equipment

The Rocky River generating and pumping plant mentioned in last year's report has been in successful operation since the spring of 1928. As the electrical capacity of the plant will not be required by the system until next year, full use has not been made of the plant this year. The reservoir was filled to an elevation 10 ft. below the maximum for the initial project. The pumps have handled several billion cubic feet of water. This project, the first of its kind in America, is probably the forerunner of numerous generating plants using in part pumped water. The project is fully described in a paper by E. J. Amberg, published in the *Journal of the A.I.E.E.*, August, 1928.

Progress in centrifugal-pump design has been similar to that in turbine design in the application of high-specific-speed runners of propeller or semi-propeller type in the range of low or moderate heads.

Testing and Research

There has been a great increase in recent years in laboratory experimental work and field testing. Several power companies as well as all the principal manufacturers now have well-equipped laboratories. There is an increasing use of models, not only for testing turbine performance but also for determining the proper design and layout of intakes, casings, draft tubes, valves, and even of an entire project, with power house, dam, tailrace, river channel, etc., all reproduced to scale.

The practice of making a field acceptance test of large turbines or of at least one of two or more similar units is becoming general, and the operating value of actual performance data is widely recognized. From June, 1920, to September, 1928, more than 175 individual turbine tests were made in the United States and Canada by the Gibson pressure-time method. About 120 wheels have been tested in the United States and Canada by Prof. C. M. Allen, using the salt velocity method, in addition to which many tests have been made by this method by power companies on the Pacific Coast.

The importance of research work, both in the laboratory and in the field, is more generally recognized.

A monumental work which should be of particular interest to those who wish to follow hydraulic research, is the report on "Hydraulic Laboratory Practice" which is being published by The American Society of Mechanical Engineers, sponsored and edited by John R. Freeman. This work consists of a translation of "Die Wasserbaulaboratorien Europas" (The Hydraulic Laboratories of Europe), with extensions of several of the original chapters to include recent researches and experiments, several appendixes describing European and American laboratories, and three appendixes treating of the principle of similitude as applied to experiments with models of hydraulic structures. It is hoped that the book will be available about the time this report is presented. The Society and hydraulic engineers everywhere are greatly indebted to Mr. Freeman for this work.

Bibliography

A complete bibliography of hydraulic literature may be found in a recent serial report of the Hydraulic Power Committee of the National Electric Light Association on "Bibliography and Manufacturers' Statements." It would be unnecessary repetition to present a bibliography with this progress report.

Other recent reports of the N.E.L.A. Committee which are of special interest to the members of this division are "Waterwheel Testing and Operating Records of Plant Discharge," March, 1928, and "Mechanical Reliability of Hydro-Electric Units," July, 1928.

Acknowledgment

The undersigned wishes to acknowledge his indebtedness and express his thanks to the many members of the Society and other engineers and manufacturers whose contributions and suggestions have been freely used in the compilation of this report.

Ralph L. Thomas.

Discussion

Byron E. White.[1] Referring to the subject of dams, the report states: "The lesson seems to be that the work of municipalities should be subjected to supervision just as much as privately owned dams. It is to be hoped that, in the effort to remedy the situation and restore public confidence in the safety of dams, extreme legislation will not be passed unnecessarily increasing the size and cost of the structures."

The writer is convinced that the following should be included so that an additional lesson may be learned from this failure:

Not only should the work of municipalities, as well as other public or semi-public enterprises, be subject to supervision by state or national commissions or competent authorities, but they should avail themselves of the services of one or preferably more consulting engineers, engineering firms, or geologists specializing in the particular type of construction or type of investigation involved and thoroughly competent to pass intelligent and final judgment upon the merits of the particular case. Privately owned works are usually constructed only after having obtained a sufficiency of competent technical advice respecting the particular engineering and geological problems presented. This is especially true of the larger and more prosperous companies, though often disregarded by smaller organizations.

It is to be hoped that this disaster, together with others which are still fresh in mind, will suffice to impress upon all engineers and executives, whether of privately or publicly owned works, the necessity, as well as the desirability, of assuring themselves so far as is humanly possible of the safety of their proposed structures, by adequate preliminary investigation, followed by competent supervision and inspection and, if necessary, further investigation during construction and even after completion.

The moral as well as legal advantage which will result from having taken all possible precautions against improper or dangerous design and construction should be obvious to any one having a sense of responsibility to his principals as well as to the public.

Tests on Small Rotary Pumps

By DIPL.-ING. F. ASCHNER and DIPL.-ING. L. MATTHEUS, BERLIN, GERMANY

GEAR pumps and other small rotary pumps are used for pumping lubricating oil, cooling water, and other liquids to all kinds of machines and especially to machine tools and steam and internal-combustion engines. Published information on the behavior of these pumps under a variety of pressures, speeds, and oil viscosities is very scarce, even though forced lubrication by means of such pumps is the basis of modern engine construction. The Mechanical Laboratory of the Technical University of Breslau has attempted to remedy this lack of data by performance and efficiency tests on these pumps under various working conditions. These tests were made on the usual types of lubricating pumps: rotary piston pumps as used on the Hispano-Suiza machine (Fig. 3) and gear pumps for machine tools and automobile engines as constructed by Ludwig Loewe, Berlin and Breuer, Hoechst a/M (Figs. 5 and 11).

The Loewe gear pump used had gears with pitch diameters of 1.575 in. and a theoretical discharge Q_{tA} of 0.87 cu. in. per revolution and was operated at various discharge pressures P_d and at speeds between 250 and 1000 r.p.m. with an oil viscosity of 250 sec. Saybolt (corresponding to a temperature of 120 deg. fahr. for the oil used in all the tests as may be seen from Fig. 4). Test results are shown graphically in Figs. 6 to 10.

The Breuer gear pump used had gears with pitch diameters of 0.95 in. and a theoretical discharge Q_{tA} of 0.19 cu. in. per revolution. Tests were run at various discharge pressures P_d between 0 and 42 lb. per sq. in., various speeds between 250 and 2500 r.p.m., and various oil viscosities between 1200 and 32 sec. Saybolt (corresponding to temperatures between 85 and 190 deg. fahr., as may be seen from Fig. 4). Some test results for a speed of 2000 r.p.m. are plotted in Fig. 12.

A Hispano-Suiza rotary piston pump with a cylinder diameter of 1.1 in., a piston diameter of 0.95 in., a cylinder length of 1.55 in., and a theoretical oil discharge Q_{tA} of 0.6 cu. in. per revolution was also tested. The range of discharge pressures P_d was 0 to 210 lb. per sq. in., the range of velocities was 250 to 2500 r.p.m., and the range of viscosities was 1200 to 70 sec. Saybolt (corresponding to 85 to 190 deg. fahr. from Fig. 4). Graphs of test results are given in Figs. 13 to 19.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., December 3 to 7, 1928, of The American Society of Mechanical Engineers.

Comments on Test Results

Values of volumetric efficiency of the pump (actual oil discharged per minute ÷ theoretical pump displacement per minute) are important design data since each moving part of the main engine requires a definite quantity of oil per minute for proper lubrication and certain engines (e.g., internal-combustion types) will be seriously affected by too much lubrication. The net efficiency of the pump (power output ÷ power input) is of less interest because the power input to the pump is very small in proportion to the power output of the main engine.

The volumetric efficiency is influenced by two principal factors, the viscosity of the pumped oil and the clearances within the pump that are due to design, manufacture, and wear. An important factor in connection with gear pumps is the effect of eddies formed at the discharge side by the operation of the gears. These, however, reduce the net efficiency only. At the higher oil temperatures and consequent decreasing viscosities, the sluggishness of the oil decreases and the influence of clearances increases. Increased pressures P_d produce a decrease in volumetric efficiency in all cases. At higher speeds the influence of oil tenacity increases and the influence of clearance decreases. It is interesting to note that the influence of the oil temperature on the volume pumped Q_r is more constant and distinct than that of the viscosity. In nearly all cases the change of Q_r caused by the 35-deg. temperature change between 85 and 120 deg. fahr. (1200 and 250 sec. Saybolt from Fig. 4) equaled the change of Q_r caused by the 35-deg. temperature change between 120 and 155 deg. fahr. (250 and 110 sec. Saybolt), other conditions being equal.

The curves give the best and clearest representation of the test results, both for individual data and general characteristics. Therefore only a short discussion of the results will be given.

The Breuer gear pump for automobile engines was tested at low pressures only. At each oil temperature and speed, the pressures at which the actual discharge and the volumetric efficiency become zero were measured. At 2000 r.p.m. this limit changed from P_d equals 70 lb. per sq. in. at a viscosity of 1200 sec. Saybolt to P_d equals 14 lb. per sq. in. at a viscosity of 32 sec. Saybolt. These higher values at greater viscosities indicate that the obtainable pressure P_d depends on the clearance losses caused by the back pressure of the oil. At $P_d = 0$, the volumetric efficiency is nearly independent of the oil vis-

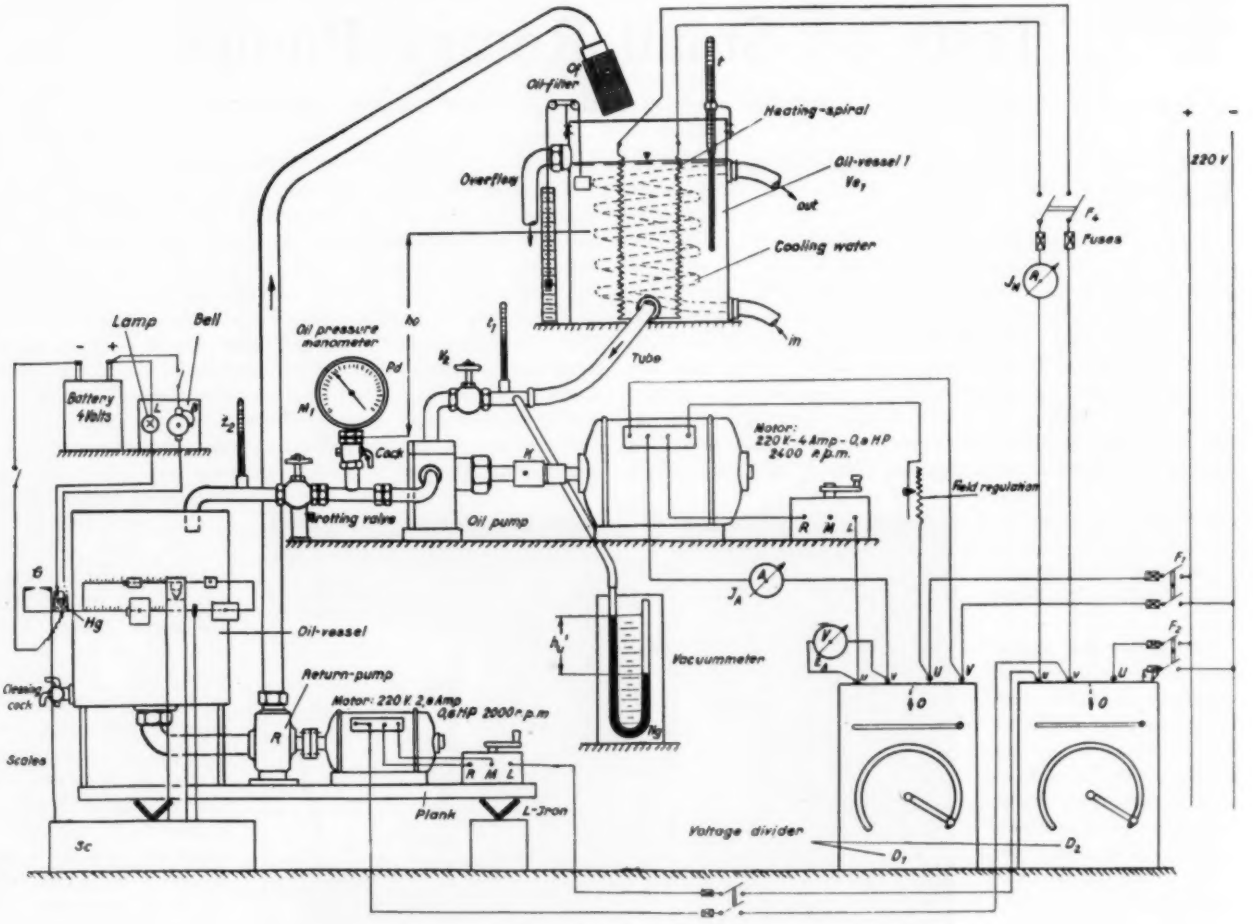

FIG. 2 DIAGRAM OF TEST APPARATUS

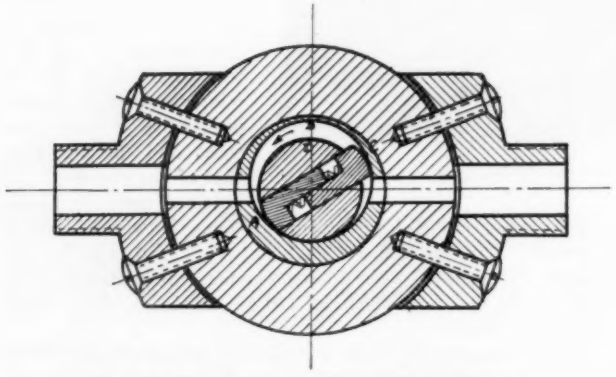

FIG. 3 HISPANO-SUIZA ROTARY PISTON PUMP

cosity and is always about 80 per cent except at lower speeds where there are maxima in excess of 90 per cent at a viscosity of 110 sec. Saybolt. At higher speeds (above 1000 r.p.m.) and at all pressures the volumetric efficiency increases with the viscosity as is shown in Fig. 12. As the discharge pressure P_d increases, the volumetric efficiency decreases, especially at low speed and low viscosity. At the testing speeds the maximum volumetric efficiency was not reached. The test results of the other two pumps need only be discussed in so far as they differ essentially from the Bteuer pump results. The volumetric efficiency of the Loewe gear pump is constant at speeds above 900 r.p.m. for pressures between 0 and 56 lb. per sq. in. At higher pressures maximum volumetric efficiencies were not reached. The highest pressure at high speed was in excess of

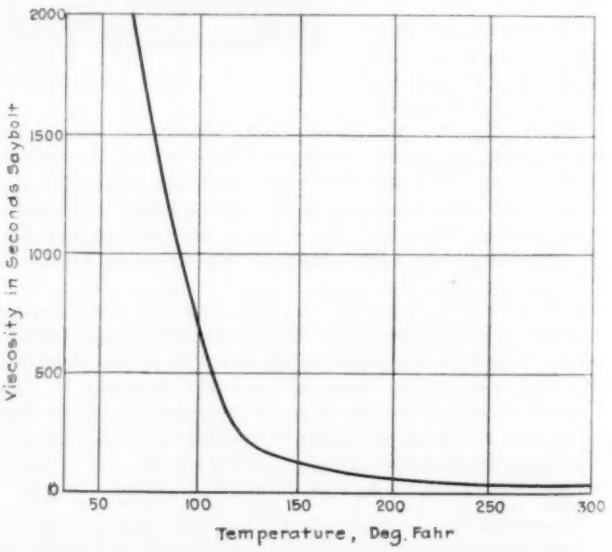

FIG. 4 VARIATION OF VISCOSITY WITH TEMPERATURE FOR OIL USED IN TESTS

170 lb. per sq. in. Speeds above 1000 r.p.m. caused excessively noisy operation.

During the tests of the Hispano-Suiza rotating piston pump, speeds higher than 1000 r.p.m. caused the pressure to mount to about 275 lb. per sq. in. at each oil temperature. This increased oil pressure produced by this kind of pump is caused by the tightening effect of the springs pressing the blades to the cylinder wall. The highest values of discharge pressure

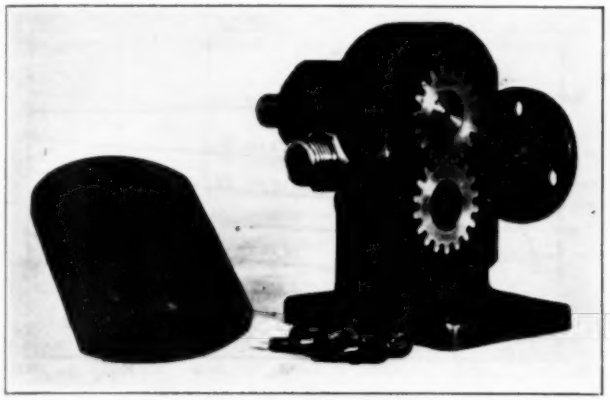

FIG. 5 LOEWE GEAR PUMP

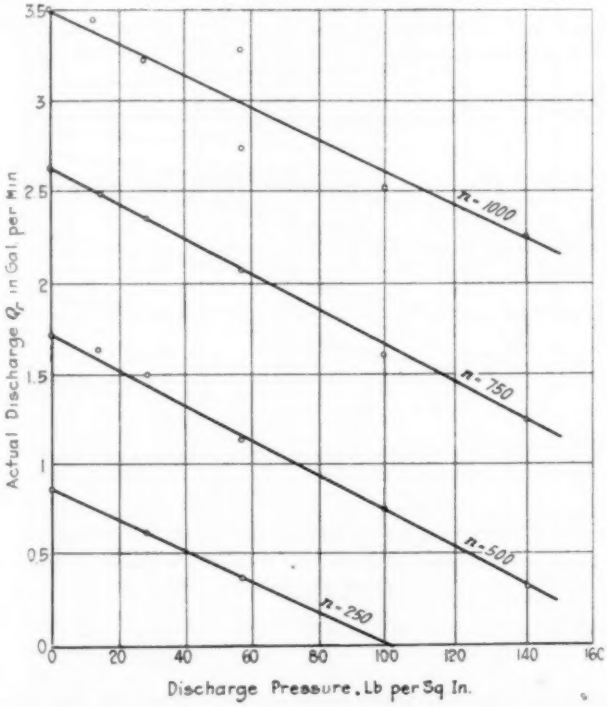

FIG. 6 VARIATION OF ACTUAL DISCHARGE Q_r AGAINST DISCHARGE PRESSURE P_d IN THE LOEWE GEAR PUMP FOR SEVERAL CONSTANT SPEEDS n

P_d at low speed were obtained (Fig. 16). At 500 r.p.m. these pressures vary from 250 lb. per sq. in. at a viscosity of 1200 sec. Saybolt to 200 lb. per sq. in. at a viscosity of 70 sec. Saybolt, i.e., the influence of the oil viscosity on the pressure of this pump is much smaller than it is on the pressure of gear pumps. However, excessive wear of the cylinder caused by the high blade pressure may occur. The volumetric efficiency shows a distinct maximum at all pressures and speeds between 1000 r.p.m. at a viscosity of 1200 sec. Saybolt and 2000 r.p.m. at 70 sec. Saybolt (Figs. 17 to 19), a phenomenon which may be attributed to the tenacity of the oil which cannot follow the rapid motion

of the blades. As this maximum is not reached in gear pumps, these latter are better adapted for the higher working speeds. Figs. 17 to 19 show curves of volumetric efficiency plotted

against actual discharge for various constant discharge pressures and speeds. These curves are useful for design purposes because they give volumetric efficiency and actual discharge for a variety of working conditions.

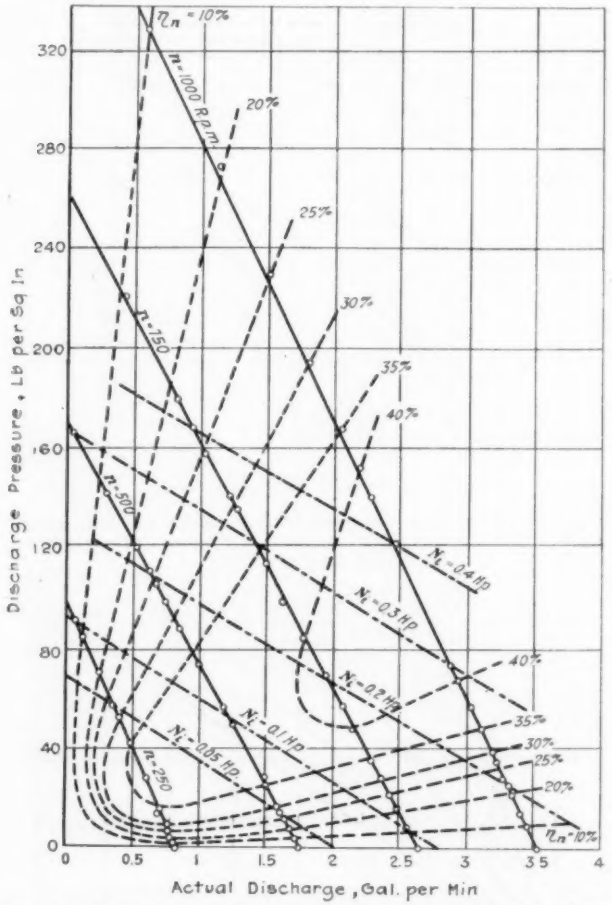

FIG. 10 VARIATION OF DISCHARGE PRESSURE OF LOEWE GEAR PUMP WITH ACTUAL DISCHARGE FOR VARIOUS SPEEDS n, NET EFFICIENCIES η_n, AND POWER INPUTS N_i

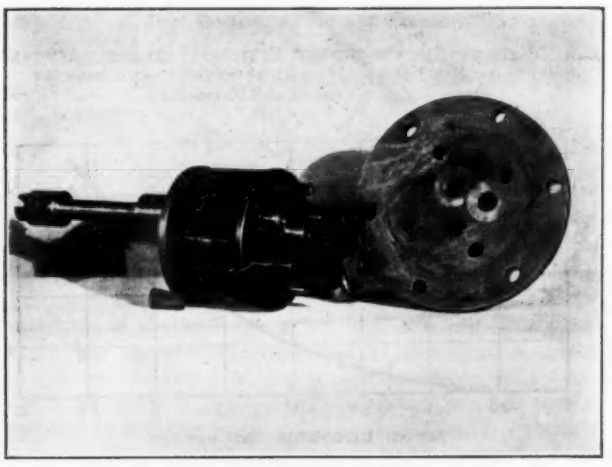

FIG. 11 BREUER GEAR PUMP

In spite of the high values of vacuum that often occur at the suction side of the pump these pumps have little suction when starting until they are primed. If convenient the oil should run to the suction side of the pump with at least a small pressure. The vacuum measured during the operation of the pump is proportional to the square of the oil velocity (Fig. 9). The power characteristic was obtained by a method used in testing centrifugal pumps (Fig. 10). Table 1 gives data for the most probable working conditions of these pumps.

The influence of viscosity has already been discussed. The volumetric efficiencies of the Loewe and Hispano-Suiza pumps are high at usual pumping conditions. The lower volumetric

efficiency of the Breuer pump can be accounted for by the small dimensions of the pump and the clearance losses which are relatively great. This kind of pump therefore should not be employed if high oil pressures are needed. A particularly good tooth formation is desirable. The influences which determine these efficiencies can hardly be calculated in a theoretical way, since the clearances depend in large measure on the design and manufacture of the pump; but, since nearly all pumps of this size resemble one of the tested types in design and construction, conclusions can be made from the test results as to the general characteristics of gear and rotary piston pumps.

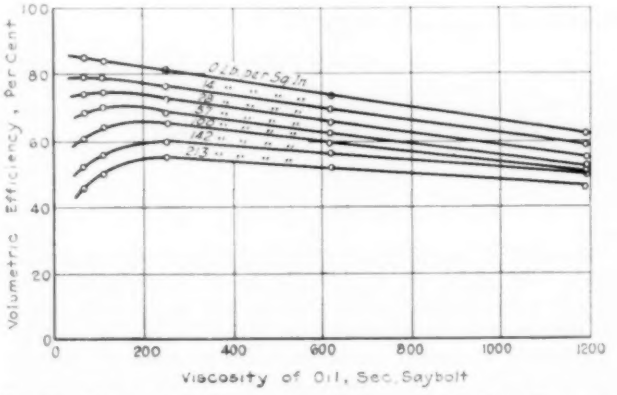

FIG. 15 VOLUMETRIC EFFICIENCY OF HISPANO-SUIZA PUMP PLOTTED AGAINST VISCOSITY OF OIL USED. VARIOUS DISCHARGE PRESSURES. SPEED = 2000 R.P.M.

ARRANGEMENT OF APPARATUS

Figs. 1 and 2 show the general arrangement of the apparatus used in conducting the test. The pump under test is directly coupled to an electric motor, the speed of which is controlled by the rheostat D_1. In the vessel Ve_1 the oil can be heated by an electric heater connected to the rheostat D_2, or it can be cooled by a water coil so that the required oil viscosity can be obtained at all times. The oil pressures on the pump can be changed by throttling of the valve V_1. Manometers M_1 and M_2 show the pressure and the vacuum produced by the pump, respectively; and thermometers indicate the temperature of the oil before entering and after passing through the pump and in the vessel Ve_1. After having passed through the pump the oil is weighed in the vessel Ve_2 by the scales Sc. The time for filling the vessel is measured by a stop watch and, since the specific weight of the oil is known, the output of the pump per

minute can be accurately calculated. The balancing of the scales is indicated by lamp L and bell B. From the vessel Ve_2 the oil is transferred by pump R to vessel Ve_1. All of these details are shown in Figs. 1 and 2.

The same oil was employed for all tests. Its properties (specific weight, viscosity, flash point) were determined, and the viscosity was varied by change of temperature according to the test requirements. Preliminary tests showed that the oil output and consequently the efficiency did not depend upon the distance of the vessel Ve_1 above the suction inlet of the pump. A small descent of the oil to the pump is necessary to avoid frequent need of priming.

Methods of Calculation and Preliminary Tests

The volumetric efficiency is the actual discharge per min. Q_r divided by the theoretical pump displacement per min.

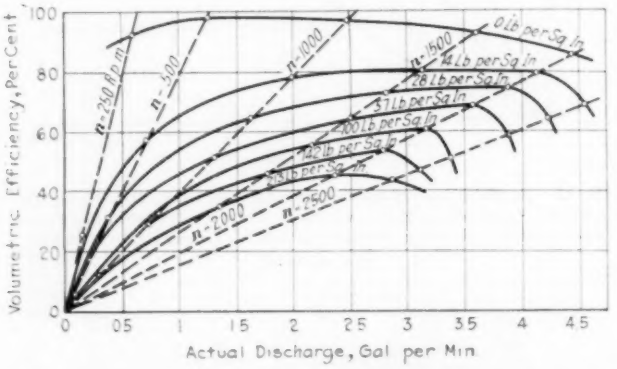

Fig. 19 Volumetric Efficiency of Hispano-Suiza Pump Plotted Against Actual Discharge for Various Discharge Pressures. Various Speeds n. Tempbrature = 190 Deg. Fahr.

Q_{th}, the result being expressed as a percentage. The theoretical output Q_{th} of rotary piston pumps is sometimes calculated incorrectly. The usual rotary piston pumps have a displacement piston eccentrically placed in a cylinder which is always divided into two chambers by blades forced out by springs (Fig. 3). The contents of the displacement chamber are discharged twice for each revolution. Calling the contents of the section $ABCD$ K sq. in. and the length of the chamber l in., the theoretical output in cu. in. per min. at n r.p.m. is given by

$$Q_{th} = 2Kln \quad [1]$$

The theoretical volumetric discharge of a gear pump is obtained by correct calculation of the double volume of liquid expelled by the teeth of one wheel from the spaces between the teeth of the other wheel. The clearance between the top of the teeth on the one wheel and bottom of the teeth on the other wheel must not be neglected. The real output of the pump Q_r in gal. per min. can only be determined by test. As previously stated the pumping time for a certain quantity of oil (20 or 40 lb.) was accurately measured by a stop watch. If this time is T seconds for 40 lb. and if γ is the specific weight of the oil in lb. per gallon, then

$$Q_r = \frac{40}{(T/60)\gamma} = \frac{2400}{T\gamma} \quad [2]$$

In these tests the effort was made to secure complete characteristics of the pumps, also data as to their power demand and net efficiency. The net efficiency equals the quotient, expressed as a percentage, of the power output of the pump divided by its power input. Since the driving motor and pump are directly coupled, the power input of the pump N_i equals the power output of the electric motor, or

$$N_i = \eta_e EI/746 \quad [3]$$

where N_i is the power input of the pump in hp., E is the motor voltage, I is the motor current in amperes, and η_e is the percentage efficiency of the electric motor. The power output of the pump is given by

$$N_o = Gh/550 \quad [4]$$

where N_o is the power output of the pump in hp., G is the rate of pumping oil in lb. per sec., and h is the head of oil in feet, that is, equivalent to the oil pressure p, which is in lb. per sq. in. The relation between p and h is

$$p = 12h\gamma/231 \quad [5]$$

where γ is the specific weight of the oil in lb. per gallon and 231 is the number of cubic inches in one gallon. Solving for h

$$h = 19.25p/\gamma \quad [6]$$

G can also be expressed in terms of γ

$$G = Q_r\gamma/60 \quad [7]$$

where Q_r is the actual discharge of the pump in gal. per min. Substituting Equations [6] and [7] in Equation [4]

$$N_e = \frac{Q_r(19.25p)}{60(550)} = pQ_r/1715 \quad [8]$$

The oil used in all the tests was tested for change of specific weight and of viscosity with change of temperature. The specific weight changed from 7.75 to 6.75 lb. per gal. when the temperature was increased from 65 to 230 deg. fahr. The viscosity as a function of temperature is shown in seconds Saybolt in Fig. 4. The flash point of the oil was 250 deg. fahr. Since the oil had a Saybolt viscosity of 1200 sec. at 85 deg. fahr., the operation of the pumps at lower oil temperatures was of no interest. The viscosity most frequently used in practice is about 250 sec. Saybolt and, consequently, this viscosity is of the most interest from the research standpoint. The test of the Loewe pump conducted at only one oil temperature was therefore carried out on oil at 120 deg. fahr. (viscosity of 250 sec. Saybolt from Fig. 4). Above 200 deg. the change of viscosity is small. The highest temperature used in the test was 190 deg. fahr.

HYD-51-3

New Aspects of Maximum Pressure Rise in Closed Conduits

By S. LOGAN KERR,[1] PHILADELPHIA, PA.

This paper discusses the various elements entering into the determination of the true maximum rise in pressure which may occur in closed conduits. It shows that, contrary to the usual belief, the maximum rise in pressure will not necessarily be produced when the full flow in a given conduit is cut off, but is a function of the initial flow from which the deceleration starts. The necessity of establishing the relation between the average conduit velocity and the rate of gate travel for various proportional strokes is cited.

Comparison is made of the computations by several of the accepted methods based on the elastic wave theory, and a translation of important studies made by M. Maurice Gariel in France is included. The application to practical cases is outlined and specific examples are worked out in detail.

A general summary of water-hammer computations is given with several simple formulas for the rapid calculation of the critical conditions.

IN CONDUITS carrying fluid under pressure where the flow may be reduced with any degree of rapidity, the resultant change of momentum will cause an appreciable increase of pressure with respect to time. This is called water hammer, and its occurrence in water-works distribution systems, aqueducts, and hydraulic-turbine penstocks is of particular interest. The safety of these conduits is of prime importance and their design should be adequate to withstand both the normal static pressure and the maximum instantaneous rise in pressure resulting from water hammer.

The investigation of the safety of penstocks in several recent hydroelectric plants has resulted in the finding of some very interesting relations affecting the determination of the true maximum rise in pressure. Contrary to the usual belief, the maximum rise in pressure will not necessarily be produced when the full flow in the given conduit is cut off. Research in this direction brings to light the fact that water hammer is a function not only of the rate at which the flow is decelerated, but is also a function of the initial opening of the control apparatus from which the closure starts. The purpose of this paper is to discuss the various elements entering into the determination of the true maximum pressure rise under such conditions.

Historical Note

The rise in pressure in closed conduits, caused by the deceleration of flow, has occupied the attention of engineers and scientists for a number of years. Numerous theories have been advanced and many formulas have been developed to solve for the maximum value of this rise in pressure. The first research, which later led to the development of the elastic-wave theory, was made by Joukovski in Moscow, Russia, and was published in English in the Proceedings of the American Water Works Association in 1904.[2] An amplification of this work, made by Lorenzo Allievi in Italy, has been published in Italian, French, and German, and recently has been translated into English.[3] Studies have been made in this country by Johnson,[4] Gibson,[5] Durand,[6] and others.

Recently Quick[7] presented a comparison of the elastic-wave theory and the various water-hammer formulas published in English up to that time. His studies also include a simple chart for the rapid solution of water-hammer problems.

Certain important researches in this field have been made in France by de Sparre[8] based on the fundamental principles as laid down by Joukovski and Allievi. De Sparre developed very simple and accurate formulas for the solution of water-hammer problems where the maximum rise in pressure does not exceed one-half of the normal head on the conduit.

Later, the mass of problems connected with the question of water hammer was taken up in great detail by Camichel,[9] Eydoux, and Gariel[10] who, by theoretical research and by more than three thousand tests made both in the laboratory and in important power plants, reached certain conclusions of highly practical importance. The work of Gariel, particularly, is of interest and will be discussed in greater detail in this paper.

General Theory

The experiments conducted by Joukovski showed that pressure waves travel up and down the length of the conduit as a result of the partial or complete stoppage of the flow of water in a closed conduit, and that their amplitude and speed of propagation are a function of the compressibility of the fluid and the elasticity of the walls of the conduit. The velocity of the pressure wave is commonly called a and is determined from the following formula:

$$a = \frac{12}{\sqrt{\frac{w}{g}\left(\frac{1}{K} + \frac{d}{Ee}\right)}} \qquad [1]$$

or for steel pipes

$$a = \frac{4660}{\sqrt{1 + \frac{d}{100b}}} \qquad [1a]$$

where

a = velocity of the pressure wave in feet per second
g = acceleration due to gravity in feet per second per second
d = diameter of the pipe in inches

e = thickness of the walls of pipe in inches
k = the voluminal modulus of elasticity of water, 294,000
E = modulus of elasticity of the material of the pipe walls = approximately 29,400,000 for steel
w = weight of one cubic foot of water in pounds.

Joukovski determined that the maximum rise in pressure in a given conduit would occur when the total flow was stopped in a period of time equal to that required for the pressure wave to travel from the point of control to the point of relief and return.

This time is commonly called μ, and is determined from the formula

$$\mu = \frac{2L}{a} \quad \ldots\ldots [2]$$

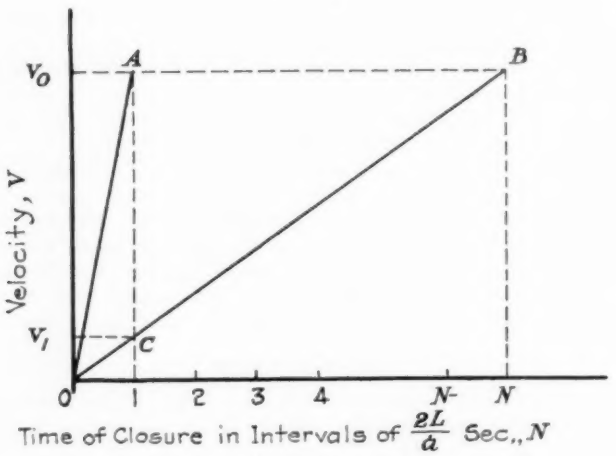

FIG. 1

where

L = length of the conduit in feet
a = velocity of the pressure wave from Formula [1].

Under these conditions the maximum rise in pressure is given by the relation

$$h = \frac{aV_0}{g} \quad \ldots\ldots [3]$$

where

h = the rise in pressure above normal in feet
V_0 = the initial velocity in feet per second
a = the velocity of the pressure wave
g = the acceleration due to gravity.

If the closure is made in a time less than $2L/a$ sec., assuming that the conduit is uniform in cross-section and in thickness, the pressure rise will not be greater, but will occur proportionately sooner and will be transmitted undiminished for a given distance along the conduit.

In commercial design, it is almost invariably the practice to prevent the deceleration of full flow from occurring at any such rate and a time is selected for the full closure of the control apparatus that permits a rise in pressure usually not in excess of one-half the normal head. In certain installations, higher values of pressure rise are permitted, but in a larger number the tendency has been toward more conservative design.

Critical Conditions

Referring to Fig. 1, if V_0 is the initial velocity in a given conduit, the line OA represents the relation of the time of closure with respect to velocity for the full flow to be cut off in $2L/a$ sec. or $N = 1$. This is the condition outlined under the heading of "General Theory" and the rise in pressure is given by Formula [3].

If this same velocity V_0 is to be decelerated in a longer time than $N = 1$, then the relation between initial velocity and time of closure is given by the line OB, where N may be any number of intervals greater than 1.

In the second case where $N > 1$, if the closure starts from some intermediate velocity V_1, less than the full velocity V_0 such that the time of closure will occur in exactly $2L/a$ sec., this condition may be shown as the line OC, Fig. 1. The rise in pressure will then be

$$h_1 = \frac{aV_1}{g} \quad \ldots\ldots [3a]$$

Thus in any closed conduit where the full flow is decelerated in a time greater than $2L/a$ sec., the deceleration of some intermediate initial flow will occur in exactly $2L/a$ sec., and the rise in pressure in this case will be given by the Joukovski formula, aV/g.

This interesting condition has not, in general, been previously appreciated. Investigation shows that the pressure rise occurring due to such a closure from a partial gate opening will be more severe than that which occurs due to closure from full gate opening in a proportionately longer time.

Practical Significance

Since the principal application of water-hammer theory is required in connection with the design of conduits feeding hydraulic turbines, this phase of the problem will be used as the basis of the examples given herein.

The use of hydraulic turbines in commercial service necessitates the rapid movement of the control apparatus, and almost any change in loading may occur during the operation of the unit. It is possible for a turbine to be operating at no load and pick up large amounts of power very rapidly; or the turbine can be operated at full gate and have any or all of its load dropped off; or it can be operating at partial gate openings and the same changes in load may occur. Thus, there is a very wide range of conditions which may take place during the normal functioning of the turbine.

The matter is still further complicated by the fact that the discharge, and hence the velocity in the conduit, may not vary uniformly with the amount of gate opening; the rate of gate travel may not be a uniform or linear function with respect to time; and the time required for partial strokes of the gate mechanism may not represent direct proportions of the full gate stroke.

From the point of view of safety of the plant and of the equipment therein, it becomes imperative to analyze just what conditions can be critical and what operations of the turbine governor and control mechanism will give the maximum pressure rise for which the water conduits must be designed.

General Assumptions

The complex nature of the problem renders it essential to make certain assumptions in order to facilitate the analysis and to avoid a great deal of computation. The special features of the more involved cases requiring detailed analyses will be taken up in another section of this paper.

Initially the studies will be based on the following assumptions for the sake of simplicity:

1 That the conduit considered is of constant thickness and of constant diameter.

2 That there are no surge tanks, air chambers, or relief valves in the conduit being considered.

3 That the loss in head due to friction is negligible.

4 That the closure of the turbine gates is a straight-line function with respect to time and no cushioning effect is present at the end of the stroke nor "dead time" at the beginning.

5 That the time required to effect a partial stroke of the gates is a direct proportion of the time required for the full stroke. That is, the closure from half gate to zero is effected in one-half the time required for the closure from full gate to zero, and that a closure from one-quarter of full gate to zero is made in one-quarter of the full gate time and so on.

6 That the discharge through the orifice and hence the average velocity in the conduit is considered to be a direct linear function of the opening of the orifice, there being no variation in the coefficient of discharge.

7 With the formulas of de Sparre, there is one further assumption necessary; the rate of closure will be such that the rise in pressure will not exceed one-half of the normal head on the conduit.

Methods of Determination

Any of the accepted methods of water-hammer computation may be used in the determination of the critical condition. They include the series of formulas developed by Allievi, Gibson, and Quick; the arithmetic integration method of Gibson; the charts prepared by Allievi and Quick; or the formulas of de Sparre when used as outlined by Gariel. These methods are most conveniently applied to uniform relations of quantity, gate motion, and time with respect to each other as outlined under the heading of "General Assumptions," but by certain corrections can be applied to non-uniform relations as well.

The series of formulas of Allievi, Gibson, and Quick and the arithmetic integration method of Gibson provide the most accurate solution for all conditions, since the actual form of the pressure curve with respect to time is developed. They entail a great deal of computation and, for this reason, are made use of only in special cases where the shape of the pressure-time curve is required.

The charts of Allievi and Quick offer a more rapid and convenient method of solution and give the maximum pressure rise for any given condition. They have some limitations, however, due to the fact that they are not available universally and, when reproduced in publications, cannot usually be read with great accuracy. This is particularly true of the Allievi chart for conditions involving fairly rapid closures from small gate openings, a serious inconvenience in determining the critical conditions for the problem now under consideration. The chart prepared by Quick is likewise subject to inaccuracies in interpretation due to the necessity of estimating between coordinate lines of all three functions involved.

The other solution, by using the formulas of de Sparre, is limited to closures that will produce pressure rises not in excess of one-half the normal head. Since the general tendency is to consider this amount of excess pressure as the limit for good design, these formulas may be used for most practical problems. They provide a rapid and accurate means of solving these problems and are recommended for use generally within their correct range of application.

Of the foregoing methods, all are familiar to American engineers, with the exception of the various formulas of de Sparre and the studies made by Gariel. The writer has been able to translate and present in this article, through the kindness of M. Maurice Gariel in granting the necessary permission, the essential parts of his solution of this problem using the formulas of de Sparre.

For convenience, the general assumptions as already outlined will be used as a basis of this analysis, and in addition the symbols in the formulas will conform to those used by Quick. The original symbols employed by Gariel will also be given, except in the conventional use of h for the rise in pressure instead of η_M and H_0 for initial steady head on the conduit instead of y_0.

In addition to the definitions given under "General Theory," the following are included for the sake of clearness:

h_{max} = pressure rise for instantaneous closure = aV_0/g ft.

P = pressure rise as a proportion of $h_{max} = \dfrac{h}{\dfrac{aV_0}{g}} = \dfrac{gh}{aV_0}$

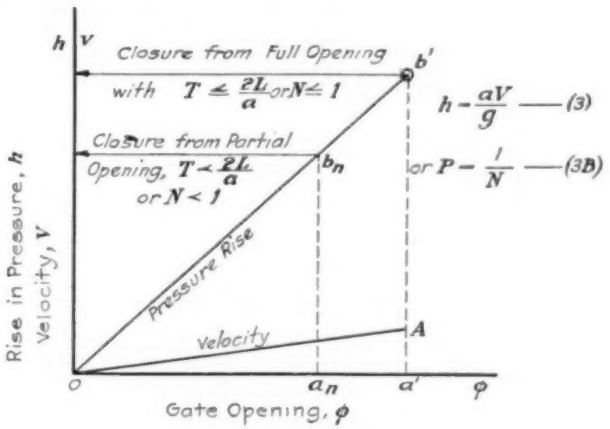

Fig. 2 Case 1

K = pipe-line constant = $\dfrac{h_{max}}{2H_0} = \dfrac{aV_0}{2gH_0}$ = ρ of Allievi

N = time constant or number of $2L/a$ intervals in time of closure = $aT/2L = \theta$ of Allievi

T = time of gate travel in seconds

ϕ = gate opening factor where $V = \phi\sqrt{H}$.

Subscripts 0 and n denote respectively initial conditions and condition at any time during closure or designating number of intervals of $2L/a$ sec.

Gariel Discussion

The following is a translation from Gariel's discussion:

Three cases should be considered—

1 Complete closure of the gates starting from full opening in a time T less than $2L/a$ ($N = 1$)

2 With a time T greater than $2L/a$ ($N \geqq 1$) and the expression $\dfrac{aV_0}{2gH_0} \leqq 1$ ($K \leqq 1$)

3 With a time T greater than $2L/a$ ($N > 1$) and the expression $\dfrac{aV_0}{2gH_0} \geqq 1$ ($K \geqq 1$)

Case 1 $T \leqq 2L/a$ ($N \leqq 1$)

Let V_0 be the velocity in the conduit corresponding to the full opening of the gates, the maximum water hammer h_{max} will be given by

$$h_{max} = \frac{aV_0}{g} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

Consider next the turbine operating at partial load and let V_n be the corresponding velocity in the conduit, evidently $V_n < V_1$ and the water hammer h_{max} corresponding to a complete closure starting from this opening will be given by

$$h_n = \frac{aV_n}{g} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3a]$$

If, as assumed in all this study, the discharge is directly proportional to the gate opening, the velocity V_n will be proportional to these same openings.

In Fig. 2 the openings ϕ of the distributor are plotted as abscissas and the velocities V of the flow in the conduit as ordinates.

The curve representing V as a function of ϕ is a straight line OA passing through the origin.

Let Oa' be the segment representing the full opening; on the ordinate of a', plot the value of the maximum rise in pressure corresponding to the complete closure from full-open position.

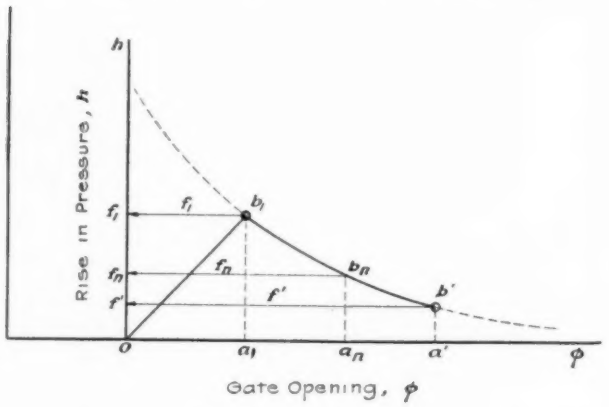

FIG. 3 CASES 1 AND 2

f_1 = closure from partial opening in time $T = 2L/a$ or $N = 1$
f_n = closure from partial opening $N > 1$ and $K < 1$
f' = closure from full opening $N > 1$ and $K < 1$
$P = \frac{1}{N + K(N-1)}$ Eq. [4b]

This maximum is equal to $\frac{aV_0}{g} = a'b'$

Let Oa_n be the segment representing any partial opening whatever; on the ordinate of a_n plot the value of the maximum water hammer corresponding to the full closure from some partial opening Oa_n. This maximum will be equal to $\frac{aV_n}{g} = a_nb_n$. Since the velocities V_n are proportional to the gate opening, the water hammer $\frac{aV_n}{g}$ will also be proportional and the line Ob_nb' is a straight line.

It may be seen, in the case where the time of full closure of the gates from full opening is less than, or at most equal to, $2L/a$, the maximum water hammer is produced on closing from full-open position, and for partial openings it decreases linearly with the value of opening from which the movement starts.

Case 2 $T > 2L/a$ and $\frac{aV_0}{2gH_0} < 1$ $(N > 1, K < 1)$

The phenomenon changes its behavior completely if the time of full closure of the gates is greater than $2L/a$ sec.

Consider first the case where $\frac{aV_0}{2gH_0}$ is less than 1 $(K < 1)$. This is the condition found with high-head plants. The maximum water hammer for full closure from full opening is given by

$$h = \frac{2LV_0}{gT} \cdot \frac{1}{1 + \frac{aV_0}{2gH_0}\left(1 - \frac{2L}{aT}\right)} \quad \ldots\ldots\ldots [4]$$

Employing the same graphic representation as previously, plot on Fig. 3 $a'b' = h$.

Consider some partial opening Oa_n corresponding to a velocity V_n in the conduit and let T_n be the time of complete closure starting from this opening. The maximum water hammer which will be produced during this closure will be given by

$$h = \frac{2LV_n}{gT_n} \cdot \frac{1}{1 + \frac{aV_n}{2gH_0}\left(1 - \frac{2L}{aT_n}\right)} \quad \ldots\ldots\ldots [4a]$$

By rearranging this expression it will be found that the equation of an equilateral hyperbola results, having for one asymptote the axis of T_n and the other parallel to the axis of h.

Having been given, by hypothesis, that the law of closure is assumed to be linear, this same hyperbola plotted with another scale of abscissas represents the variations of the maximum rise in pressure as a function of the opening from which the closure starts. This hyperbola is shown on Fig. 3. It is essential to note that this hyperbola does not represent the phenomenon of maximum water hammer except in one portion determined from one of its limits. It has been shown above that Formula [4] does not apply unless time T_n is greater than $2L/a$ and the expression $\frac{aV_0}{2gH_0}$, $(k \geqq 1)$.

Starting from the opening Oa_1 such that the total closure is effected in the time $2L/a$, all openings smaller will fall under Case 1 and the curve representing the maximum is reduced to the straight line Ob_1. For the closure b_1f_1 effected in the time $T_1 = 2L/a$ or $N = 1$ the maximum rise in pressure is equal to aV_1/g. For closures starting from openings greater than the critical opening Oa_1, the maximum pressure rise will be quite appreciably less than a_1b_1. The greater the opening from which the closure starts the less the pressure rise will be. It will reach a minimum if the velocity V_0 is such that the expression K is equal to 1. Starting from the point where K is greater than 1, the preceding considerations no longer apply and the solution falls into the third case.

Case 3 When $T > 2L/a$, $\frac{aV_0}{2gH_0} > 1$ or $N > 1, K > 1$

This is, in general, the case for low-head plants. The rise in pressure h is given for complete closure from full opening by the formula

$$h = \frac{2LV_0}{gT} \cdot \frac{1}{2\left(1 - \frac{LV_0}{2gTH_0}\right)} \quad \ldots\ldots\ldots [5]$$

and for full closures starting from partial openings

$$h = \frac{2LV_n}{gT_n} \cdot \frac{1}{2\left(1 - \frac{LV_n}{2gT_nH_0}\right)} \quad \ldots\ldots\ldots [5a]$$

It can be seen that the quantities V_n and T_n come into the expression only by the ratio V_n/T_n. As the closure has been assumed linear, this ratio is constant and hence the rise in pressure is constant from any opening from which the closure starts.

Taking an installation in which for full opening $T > 2L/a$ and $\frac{aV_0}{2gH_0} > 1$ or $N > 1$ and $K > 1$, the diagram of the maximum pressure rise may be shown as a function of the gate opening from which the closure starts.

Let Oa' be the full opening, then $a'b'$ is the maximum rise in pressure corresponding to the full closure.

If Oa'_n is a partial opening such that $K > 1$, the maximum water hammer corresponding to the partial closure f'_n will be the same as for the full opening, hence $a'_nb'_n = a'b'$ and the

curve of the maximums will be a straight line parallel to axis of ϕ.

It may readily be shown that for all conditions where the rise in pressure is not in excess of one-half the normal head, all closures in a time of $2L/a$ sec. will fall in the case where $K < 1$, hence there will always be a condition for Case 2 if the time of closure is greater than this critical time.

In the case of the diagram shown in Fig. 4 where $K > 1$ for full gate opening, there must be a partial opening a_c corresponding to a time greater than $2L/a$ for which $K = 1$. For all openings less than a_c, $K < 1$ and the solution will fall under Case 2.

Where the gate opening Oa_1 represents a closure in exactly $2L/a$ sec. ($N = 1$) the rise in pressure will be a maximum, and for closures from gate openings less than this value, the solution will fall under Case 1.

Fig. 4 represents a complete picture of three possible cases for water hammer in any conduit.

Quoting directly from Gariel:

> All the formulas and conclusions given herein apply to conduits having constant thickness of walls and constant diameter. The tests which we made at Soulon with MM. Camichel and Eydoux have shown that the general theories of MM. Allievi and de Sparre can be applied with very close approximation to conduits with constant diameter but variable thickness (a condition most frequently found in hydraulic installations) in all cases where the duration of closure is greater than $2L/a$, or slightly less than this value (a being taken as the average velocity of the pressure wave for the various sections of the conduit).

Conversion to Nomenclature of Quick

Formulas [3], [4], and [5] can be expressed in the terms as given by Quick.

For Case 1 where $K < 1$ and $N < 1$, Formula [3] reduces to

$$P = 1 \quad \ldots\ldots [3b]$$

indicating for any time of closure equal to or less than $2L/a$ sec. the maximum possible pressure rise for the given velocity will be attained.

It is interesting to note that this is identical with the formulas of Vensano and Warren as simplified by Quick for the case where $N = 1$.

In Case 2 where $K < 1$ and $N > 1$, Formula [4] reduces to

$$P = \frac{1}{N + K(N-1)} \quad \ldots\ldots [4b]$$

In this case if $N = 1$, the formula gives the same result as Formula [3b] and for $K = 1$ the same result as Formula [5b].

In Case 3 where $K > 1$ and $N > 1$, Formula [5] reduces to

$$P = \frac{1}{2N - K} \quad \ldots\ldots [5b]$$

At $K = 1$ this gives the same result as Formula [4b]. And at the respective limits of application, if $N = 1$, then $P = 1$, and if $K = 1$, then $P = \dfrac{1}{2N-1}$.

In each case care should be taken to determine P and hence h for the correct initial velocity from which the closure starts.

Typical Application of Theory to Specific Problems

It will be seen from the foregoing discussion that three basic formulas may be used for the solution of virtually all water-hammer problems which occur in normal practice. It would be of interest to apply these three formulas to a specific case and compare their solution with the results obtained from the chart prepared by Quick. A comparison will also be made between the results secured by both these methods and those determined by the arithmetic-integration method of Gibson giving the development of the actual shape of the curve of pressure with respect to time, from which the maximum values can be obtained (Table 1).

The specific example selected shows very clearly the points brought out in the previous discussion and at the same time represents a typical condition which may be found in actual practice.

The problem is based on a single unit operating under a head of 233 ft. with a penstock 600 ft. in length, of uniform cross-section, with the thickness of the pipe walls also uniform and a velocity of the pressure wave equal to 3000 ft. per sec. By assuming that the discharge is a direct linear function of the amount of gate opening, and that the rate of gate movement is also linear with respect to time, the various conditions will

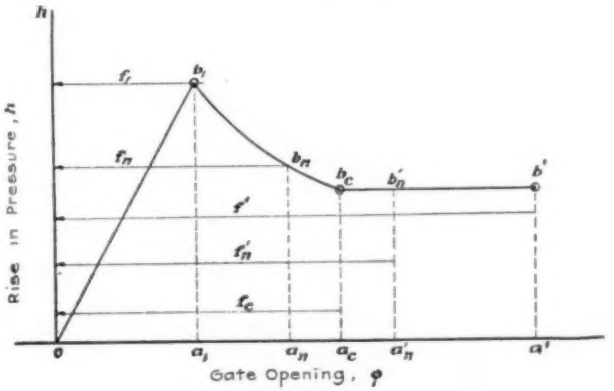

Fig. 4 Cases 1, 2, and 3

Case	Closure	K	N	Rise in pressures
1	f_1	<1	=1	$P = 1$ Eq. [3b]
2	f_n	<1	>1	$P = \dfrac{1}{N + K(N-1)}$ Eq. [4b]
2,3	f_c	=1	>1	$P = \dfrac{1}{2N-1}$
3	f'_n	>1	>1	
3	f'	>1	>1	$P = \dfrac{1}{2N-K}$ Eq. [3b]

coincide with the general assumptions as outlined at the beginning of this discussion. This same problem will later be applied to cases where the discharge is not a linear function with respect to time, and the effect of a non-uniform rate of gate movement will also be discussed.

The full-load velocity is taken as 10 ft. per sec., and since the critical time $2L/a = 0.4$ sec., a closure in 4 sec. will make $N = 10$ intervals of $2L/a$ sec. The relation of quantity, velocity, and gate opening with respect to time for this example is shown in Fig. 5.

The value of K at full load is equal to 2.0, and hence the point of inflection of the envelope curve will occur at one-half gate opening at the point where K is equal to 1. N is equal to 1 at 0.1 gate, which represents an appreciable amount of gate opening on the turbine.

TABLE 1 COMPARISON OF RESULTS OF COMPUTATIONS BY VARIOUS METHODS

Initial velocity, ft. per sec.	Time of closure intervals	Rise in pressure in feet — Formulas of de Sparre-Gariel	Charts of R. S. Quick	Arithmetical integration, Gibson
10	10	51.8	51.8	51.5
9	9	51.8	51.8	..
8	8	51.8	51.0	..
7	7	51.8	51.0	..
6	6	51.8	51.2	..
5	5	51.8	53.8	54.1
4	4	58.2	59.6	..
3	3	66.5	67.4	68.0
2	2	77.7	78.5	..
1	1	93.3	93.2	93.26
0	0	0.0	0.0	0.0

Referring to Fig. 6, the values from Formula [3*b*] are plotted as well as those obtained from Formulas [4*b*] and [5*b*]. It will be noted that the respective formulas give the same result at the points corresponding to the end of the limits in which they are applicable. Thus we have a curve *AB* for Formula [5*b*], *BC* for Formula [4*b*], and *CD* for Formula [3*b*].

Taking the solution of these same closures from the chart prepared by Quick and in each case plotting the maximum value as an ordinate opposite the abscissa corresponding to the initial point from which the closure starts, it will be found in every case from *A* to *B* that the solutions from the charts of either Allievi or of Quick agree exactly with those secured from the Formula [5*b*]. Between the points *B* and *C* there are light discrepancies, but not serious. It is interesting to note, however, that at point *C* all of the solutions agree exactly. Points *C* correspond to a velocity of 1 ft. per sec. and the closure occurs

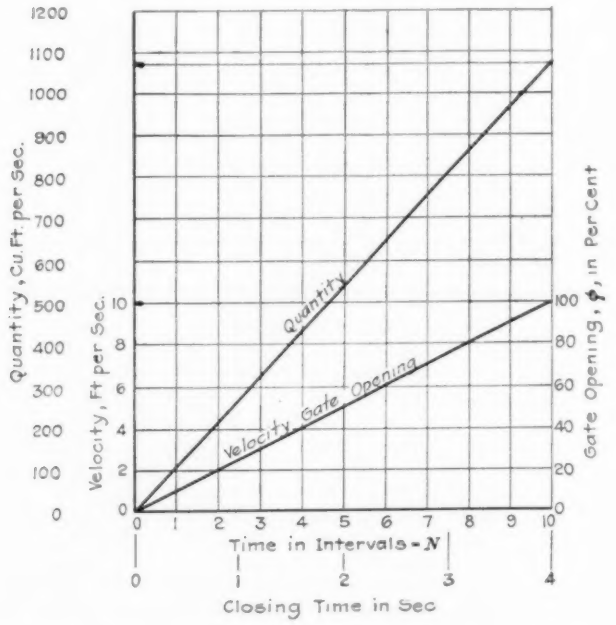

Fig. 5 Uniform Relation of Quantity, Gate, and Time

in 0.4 sec., resulting in a pressure rise of 93.26 ft. From *C* to *D*, the pressure rise is naturally reduced uniformly due to the fact that the initial velocity is directly proportional to the time of closure, since the closing time is less than $2L/a$ sec. and the pressure rise is directly proportional to the velocity destroyed.

Further to confirm these values, the various curves of pressure with respect to time for different closures at a uniform rate are shown on this same figure. Designating each of these curves in terms of the corresponding value of *N*, it will be noted that the curve $N = 10$ reaches a maximum of 51.5 ft. during the fourth interval after the closure begins, and from the fourth to the tenth interval the value remains constant. This compares with the rise of 51.8 ft. secured from the formulas or from the charts and is in substantial agreement therewith.

With the closure starting from $N = 5$ with a velocity of 5 ft. per sec. and a closure effected in 2.0 sec., the shape of the curve of pressure with respect to time changes materially and reaches the maximum of 54.1 ft. during the second interval, then decreases, and finally remains constant for the last two intervals. For the curve $N = 3$, the closure is effected in 1.2 sec. and the maximum is reached at the end of the first interval, followed by an abrupt surge downward during the second interval and upward during the third.

For the closures from $N = 10$ to include $N = 5$ the initial velocity was such that *K* has always been greater than unity and in each case it may be seen that the maximum rise in pressure is approximately the same although it is reached earlier in the stroke as the value of *K* approaches unity.

Starting at point $N = 5$ the shape of the curve of pressure with respect to time changes abruptly. The curve shown as $N = 3$ is a striking example of this fact. The maximum is reached at the end of the first interval of time and is equal to 68.0 ft. instead of 51.5 ft. as secured before, an increase of 32 per cent.

Reaching the critical point of $N = 1.0$ and a value of $K = 0.2$, the curve of pressure with respect to time increases rapidly and reaches a peak at the end of the closure, which of course is the end of the first interval of time. A maximum pressure of 93.26 ft. results, or 81 per cent in excess of that secured for the closure from full gate. At $N = 0.5$ the maximum rise is just one-half of that value, namely 46.53 ft.

This indicates in a very striking manner the possibility of securing pressure rises far in excess of those corresponding to the full gate closure.

Comparison With Energy Formula

It is interesting to note at this time a comparison between the conventional formulas which have been used in the past for determining the maximum rise in pressure from an energy basis.

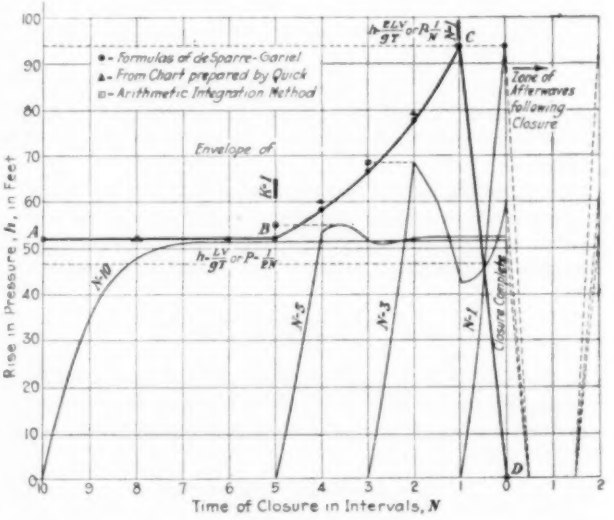

Fig. 6 Typical Problem With Uniform Relations of Quantity, Gate, and Time

The early formula of $h = LV/gT$ gives a value of only 46.63 ft. which is less than that resulting from full gate closure. The other formula, which is sometimes called Michaud's formula, $h = 2LV/gT$, gives exactly the maximum pressure rise occurring at the critical point $N = 1$ where the value of 93.26 ft. was reached.

This brings out a rather unusual relation that may be verified by any number of similar examples, namely, that this simple formula $2LV/gT$ does give the actual maximum rise in pressure which may be obtained in any given conduit at some point due to a closure from some partial gate opening.

Gariel draws particular attention to this relation and mentions that this latter formula was first developed by Michaud

in France[11] about fifty years ago, and that it is possibly the oldest of formulas for water hammer and one which has occupied the attention of engineers for some time. Experience has shown that this formula should be corrected for certain specific closures since it gives results which are too high in every case, except for closures in the critical time $N = 1$. The studies which have been made from time to time confirm the conclusion that this formula is incorrect and show that a variable correction factor must be applied depending upon the given conditions. For this reason the formula has been practically abandoned by engineers.

It is interesting to take this formula, which has so often been discredited, and substitute for the value of T the time required for a pressure wave to travel from the point of control to the point of relief and return, namely, $2L/a$ sec., and let the velocity V be equal to the amount cut off in this time.

$$h = \frac{2LV}{gT} = \frac{2LV}{g} \cdot \frac{a}{2L} = \frac{aV}{g}$$

The formula is reduced to the basic theory as developed by Joukovski and Allievi.

The various researches conducted by Camichel, Eydoux, and Gariel show that this formula should not be abandoned and that while empirical in its origin and inaccurate in its application, it is actually in close agreement with the most complete modern theories, and furthermore has been carefully verified experimentally.

It will be seen that the relation of V/T in this formula is constant, and so long as the relation of velocity to time is a linear function, this ratio will have the same value regardless of the initial opening.

It may not necessarily, and usually will not, give the correct value of rise in pressure corresponding to the deceleration of the full quantity in any given case, but it will give the maximum that must occur in any given conduit where the gate motion is uniform with respect to time and where the discharge is also a uniform function in respect to gate opening.

This offers a simple but effective means of computing the maximum possible rise in pressure in any given conduit for any particular value of velocity and time, provided that the time of closure is equal to or greater than $2L/a$ sec.

It should be emphasized, however, that this condition is true only with the uniform gate motion with respect to time and with uniform variation of discharge with respect to gate motion.

It is interesting to convert both of these two simple relations to the nomenclature used by Quick.

Thus

$$h = \frac{LV}{gT} \text{ reduces to } P = 1/2N \ldots\ldots\ldots [6]$$

This is the Formula [5*b*] if the time N is large with respect to the pipe constant K, indicating that for slow closures the simple "acceleration" relation is approximately correct.

Also

$$h = \frac{2LV}{gT} \text{ reduces to } P = 1/N \ldots\ldots\ldots\ldots [7]$$

which is identical with the formulas of Vensano and Warren, and represents the limit of Formula [4*b*] as K decreases with respect to N. For the case where $N = 1$, then $P = 1$ and it becomes identical with Formula [3*b*].

If a column of water is considered to be a rigid body, then the relation in Formula [7] will result from a mathematical analysis of the complete deceleration of the flow, showing the agreement between the elastic-wave theory and the rigid-column theory at this one point where the closure is made in $2L/a$ sec. One might be led to conclude that at some particular rate of closure the water in the conduit would behave as a rigid column. Since it has been shown that this relation is true only at $N = 1$, then the further conclusion might be reached, namely, that the water in the conduit for such a closure actually would be a rigid column.

[11] Michaud, Bulletin de la Société Vaudoise des Ingenieurs et des Architectes, 1878, nos. 3 and 4. Also Bulletin Technique de la Suisse Romande, February 10 and 15, 1903.

Partial Closures

The question naturally arises in studying this phenomenon of critical closures, if the closure from 10 per cent to zero produces such an unusual rise in pressure, does not a closure from 100 to 90 per cent in the same time produce the same rise? It

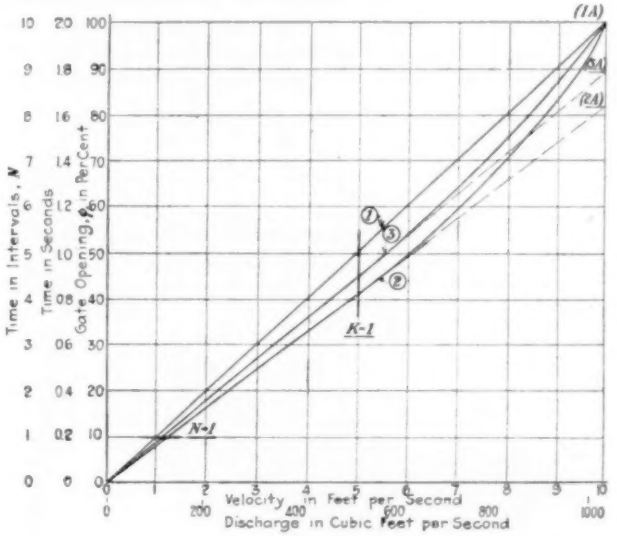

Fig. 7 Typical Relations of Gate Opening and Discharge

can be stated confidently that such cannot be the case. By referring to Fig. 6, if the closure stopped at 90 per cent on the curve $N = 10$, the rise in pressure would equal only 35 ft., the after waves would have this amplitude, and the pressure would not increase above this value.

In the case of $N = 5$, the pressure rise for a 10 per cent stroke starting from 50 per cent gate would be about 53 ft.; for a stroke starting from 30 per cent 68 ft.; and from 10 per cent gate about 93 ft.

Thus the rise in pressure for partial closures from partial gate openings is also a function of the initial gate from which the movement starts; the same as for complete closures.

After-Waves

Although the gate movement stops, the pressure waves set up due to closure will continue to oscillate until they are damped out by internal friction. They form "after-waves" with a fixed period of $4L/a$ sec. and with an amplitude usually equal to the final pressure rise existing at the instant the gates have stopped moving. For non-uniform motion, since the amplitude and wave form will be affected by the sequence and amplitude of the individual waves during closure, the after-waves may take peculiar forms. This can only be determined by the detailed computation of the individual waves by the arithmetic integration method, or by the use of the series of formulas of Allievi, Gibson, and Quick.

Non-Uniform Discharge—Gate Relation

In actual practice the ideal condition of uniform relation of velocity gate and time is rarely encountered, since the discharge generally tends to increase directly with the gate opening up to a certain point and then continues to increase, but at a slower rate with additional gate openings until a point is reached where a further opening of the turbine gates results in no increase in discharge.

Assuming for the time being that the movement of the gates with respect to time is still uniform, it becomes apparent for the same discharge at full gate opening that the discharge at fractional gate openings will be greater than would be the case if the discharge varied uniformly with respect to time, or as a linear function rather than a variable function as is actually found in practice.

In Fig. 7 are shown two non-uniform gate-discharge relations which would be typical for a turbine operating under the conditions given in Fig. 5. The uniform relation of discharge and gate is shown as Curve 1 for comparison. Curve 2 is the usual

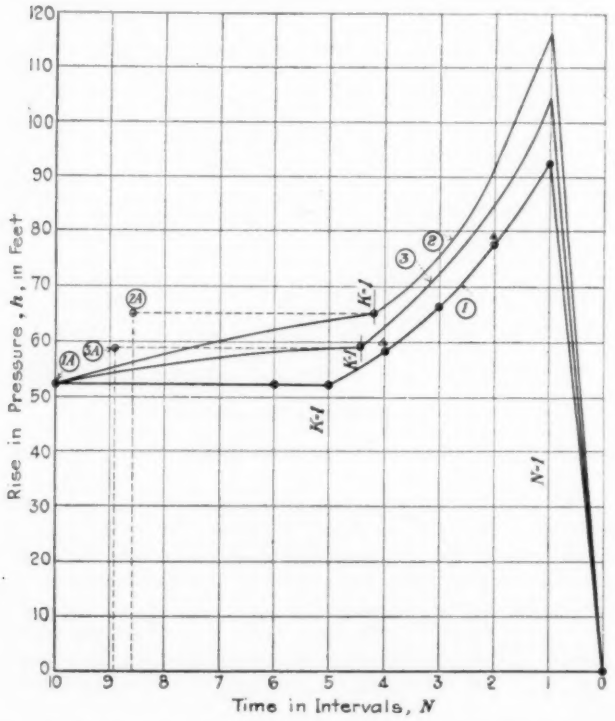

Fig. 8 Variation in Pressure Rise for Different Gate Opening-Discharge Curves

form of discharge gate relation with full gate fixed by the extreme maximum power that could be obtained from the unit. Curve 3 is the same type of unit, but with full gate fixed as the upper limit of the range of economic operation.

It will be noted on the three curves that the point where $K = 1$ occurs at the same discharge, but at different gate openings, while the point where $N = 1$ occurs at the same gate opening, but the discharge is much greater for the non-uniform relations than for the uniform relation.

Taking these three curves, and applying the Formulas [3*B*], [4*B*], and [5*B*], the envelopes of the maximum values of pressure rise may be computed. The results of these computations are given in Fig. 8 as Curves 1, 2, and 3, corresponding to the respective curves in Fig. 7.

It is interesting to compare the values of maximum pressure rise resulting from Curves 2 and 3 with the previous values obtained in Fig. 6, and shown as Curve 1 in Fig. 7. The maximum rise in pressure due to the closure from full gate is the same in all three cases, but for closures from smaller gate openings the discharge is sufficiently greater for the non-uniform relations to increase the pressure rise appreciably.

At the point where $K = 1$, the discharge is the same in all three cases, but the rise in pressure is greater with non-uniform motion since this discharge occurs at smaller gate openings, and the time of closure is correspondingly smaller.

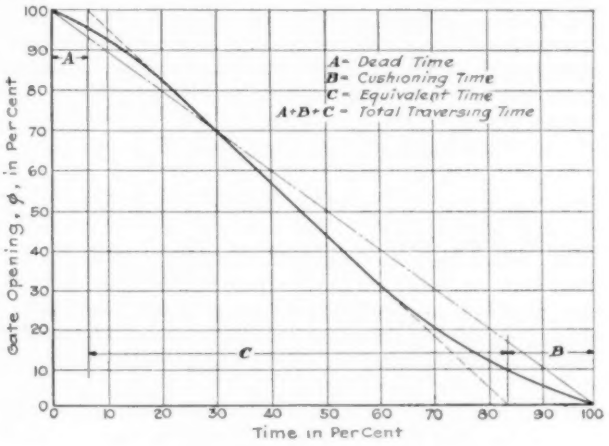

Fig. 9 Typical Gate Motion
(A = dead time; B = cushioning time; C = equivalent time; $A + B + C$ = total traversing time.)

At the point where $N = 1$, the gate opening is the same for all three cases, and the time of closure is also the same, but the discharge being successively greater, the pressure rise will also be greater at this point.

The development of this envelope may be simplified greatly by noting an interesting relation.

The curve of discharge with respect to gate opening is really a straight line for some distance starting from zero, and as the point of maximum efficiency of the turbine is approached the discharge tends to decrease for a given increment of gate opening and causes the relation to depart from the straight line and assume a curved form. If, then, the straight portion of the curve is extended until the value of full gate discharge is reached, the curve of discharge with respect to gate becomes a uniform relation, and it is necessary only to compute, as with the example in Fig. 6, the critical points by the Formulas [3*b*], [4*b*], and [5*b*]. The corresponding values of time and gate openings are used, and the envelope curve determined from the rise in pressure at the equivalent full gate $2A$ and $2B$ and the points $K = 1$ and $N = 1$.

Non-Uniform Gate Motion With Respect to Time

If the third variable is considered, namely the rate of gate movement with respect to time, still further corrections must be made. In the first place, it will be of interest, as well as for the sake of clearness, to indicate and define the various factors entering into gate movement. There is first the total time elapsed between the initial movement of the gates and their coming to rest. This may properly be called the "total traversing time" of the governor as shown in Fig. 9. It will be noticed that there is a lag of the gates in their initial movement which is present until the inertia of the mechanism has been overcome, after which the gates are usually moving at a uniform rate for the

major portion of the stroke, and then a cushioning effect begins which slows down the movement toward the end of the stroke. This characteristic is found in most governors and gate-operating mechanisms, although it has been the practice of some manufacturers to omit the cushioning effect at the end of the stroke.

If the straight portion of the curve, corresponding to the maximum rate of movement, is extended as a straight line until it intersects the initial and final values of gate opening, a new time results which represents that required for the same amount of gate travel at a uniform rate corresponding to the maximum rate attained during the stroke. This may be designated as the "equivalent time." It is this time which actually determines the maximum rise in pressure, since the maximum rise in pressure is a function of the rate of gate movement and not of the total time of travel. Where the gate motion is of this general form, then the equivalent time is approximately 75 to 85 per cent of the total traversing time.

The difference between the total traversing and the equivalent time is made up of two parts, the first being the additional time required to accelerate the mechanism, usually called the "dead time," and the "cushioning time" occurring at the end of the stroke.

The maximum rate of gate movement is attained in the major portion of the gate stroke for practically every closure, except those starting from very small gate openings. Having once determined the time and the corresponding gate travel required for acceleration and for the deceleration of the parts, it is possible to fix the minimum time and hence the minimum amount of gate stroke during which this maximum rate will be reached, which may affect the rate of closure for $N = 1$ and reduce the pressure rise at this point.

Ideal Gate Motion

Instead of an envelope curve such as that shown in Fig. 6 or Fig. 8, a uniform relation of maximum pressure rise can be obtained by adjusting the rate of gate motion for different portions of the stroke, so that the time of closure will limit the actual maximum rise in pressure to any given value.

Referring again to Fig. 6, the maximum pressure rise is constant from A to B. The extreme maximum is reached at C and then decreases uniformly to zero at D. If the time of closure for the discharge corresponding to 10 per cent gate in this particular problem is increased, so that a closure takes place in approximately twice this time, the point C will occur at $N = 2$ and the maximum value will be about the same as that secured in the range from $N = 10$ to $N = 5$. The actual pressure rise for $N = 1$ will be somewhat less than 51.5 ft. due to the slowing up of the gate motion in this range.

Between B and C the closures should take place at progressively slower rates until the minimum rate of motion between C and D is reached. The ideal relation of gate opening with respect to time of closure is shown in Fig. 10, and the letters designating the respective points corresponding to those given in the envelope curve in Fig. 6. The slope of the line AB is determined from the first derivative of the relation of velocity with respect to gate opening for normal closures, such that the rise in pressure in this range of operation will equal the desired amount. The slope of the line CD is determined from another relation of velocity with respect to time to reduce the value of pressure rise to the amount permitted by the rate from A to B. The curve between B and C will take somewhat the form as shown, and sufficient points can be determined at intermediate values of gate opening to establish the shape of this curve.

There are a number of ways in actual practice of securing this form of gate motion, among them being a throttling valve which is operated by the gate mechanism to reduce the flow of governor fluid to the operating cylinders within the range from B to D. This has also been accomplished by providing two governor pumps without accumulator tanks with the capacity of one pump sufficient only to give a rate of movement such as that shown at CD. The two pumps combined will increase the rate of travel to that shown from A to B, while the intermediate section from B to C is taken care of by the throttling of the discharge from the second pump. Still another method combines an improved design of levers and links with a specially designed cushioning effect built into the operating cylinders.

In any event, it is highly important to reduce the rate of gate travel in the critical portion of the stroke, or else to provide for additional strength in the water conduit sufficient to withstand the excess rise in pressure caused in this zone for uniform motion.

Speed Regulation

The relation to the problem of regulation is of interest, since these studies further emphasize the fact that the governor time or the rate of gate travel with respect to time in each installation should be determined from a consideration of the physical constants, such as the strength and allowable factor of safety of the conduit, the head on the plant, and the velocity in the flow line.

With these factors determined, the problem of speed regulation is a function only of the flywheel effect of the rotating element and the permissible speed variations for different load changes on the unit.

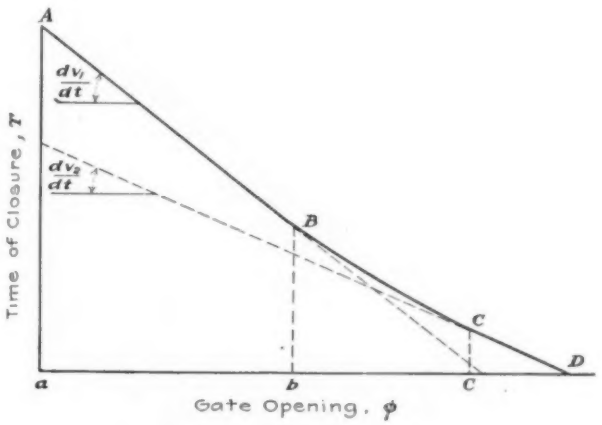

Fig. 10 Ideal Gate Motion

Improvements in regulation may come from devices which will reduce or limit the "dead time" by bringing the gate mechanism up to its maximum rate of travel without introducing any appreciable lag. This would tend to reduce the speed variations for small load changes, but the actual hydraulic conditions subsequent to this rapid travel for small load changes might actually cause a certain amount of instability due to the presence of the after waves.

Typical Application to a Given Installation

One of the most interesting applications of this theory was made in connection with the preliminary design of a recent hydroelectric plant, the Saluda development of the Lexington Water Power Co. This particular plant will operate under a maximum head of 180 ft. and the dam is of the earth-fill type with individual penstocks for each of the units carried through the base. Some of the units will be provided with surge tanks, while on others the surge tanks will be omitted. It is imme-

diately apparent that the safety of the plant depends primarily upon the safety of the conduits underneath the dam.

With this in mind, it was essential to investigate every possibility for excess water hammer. The studies were based on the application of a normal type of turbine to each conduit with a discharge-gate-opening curve somewhat on the order of that given in Fig. 7, Curve 2. The studies also assumed at first that the travel of turbine gates would be uniform with respect to time to simplify the computations. In Fig. 11*a* is shown, for a unit without a surge tank, the analysis of the pressure rise conditions for various closures from full gate to zero plotted with maximum pressure rise as ordinates and the per cent of maximum gate opening as abscissas.

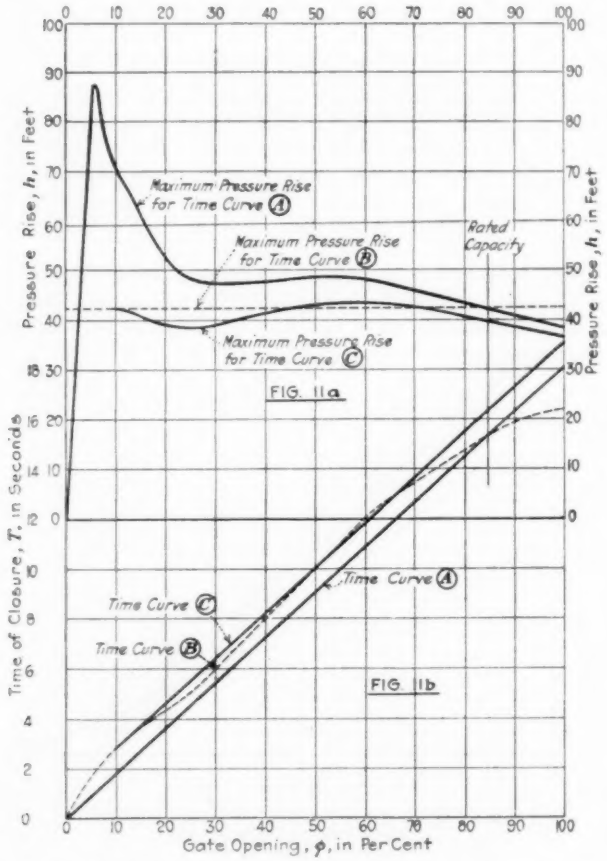

FIG. 11 WATER-HAMMER ANALYSIS OF UNIT WITHOUT SURGE TANK, SALUDA DEVELOPMENT

(Head = 180 ft.; Q = 3100 c.f.s.; avg. vel. = 15.85 ft. per sec.; L = 1179 ft.; a = 2545 ft. per sec.; T = 15.3 sec., uniform motion.)

Curve A results from the use of uniform motion with respect to time. A maximum pressure rise of 42.5 ft. above normal was fixed as the limit for safety, shown as Curve B in Fig. 11*a*. Computations were made to determine the correct time of closure starting from each gate opening to prevent the pressure rise from exceeding this value. The resultant curve of closing time with respect to gate opening is shown as B, Fig. 11*b*. It will be noticed that the allowable time of gate movement from 30 per cent to zero is very much longer than that resulting from uniform motion. It would not be practical, however, to have such an extremely variable rate of closure for different portions of the stroke, and a third curve shown as C in Fig. 11*b* was determined as being a commercial possibility. This curve is uniform with respect to time from 100 to 10 per cent, and from 10 per cent to zero a still slower rate is used. The corresponding maximum pressure rises for this form of gate motion are shown as Curve C, Fig. 11*a*.

The time as shown in Curve C represents the equivalent time as outlined in Fig. 9, and in order to convert these studies to the actual form of non-uniform gate motion, a certain increment of time was added to Curve C to take care of the "dead time" and "cushioning" time, thus giving the traversing time.

OTHER APPLICATIONS OF THE THEORY

The study of the water-hammer conditions which may occur in hydraulic turbine penstocks can be applied equally well to the problems arising from the variation of flow in closed conduits used in water-works service. In controlling the flow in such a conduit by means of a valve, the discharge is not appreciably affected by the closure of the valve until the area is reduced considerably and the actual loss through the valve assumes fair proportions. As this point is reached, the flow conditions in the control valve are similar to those occurring with free-discharge valves, since the velocity through the valve itself is very great. It is therefore important to analyze the rate of closures which occur, starting from relatively small openings of the valve, since these in turn cause the maximum variation in velocity in the conduit. The last portion of the stroke may change the flow in the conduit far more than the same amount of stroke at the fully open position.

The same methods of procedure can be used in analyzing this problem as are employed with hydraulic-turbine penstocks, but the loss in head through the valve for different openings becomes the determining factor and from this relation the variation in velocity and discharge through the valve can be established.

RELATION TO PREVIOUS PRACTICE

In view of the critical conditions of pressure rise for closures from partial openings, the question naturally arises as to why this particular characteristic has not caused an unusual amount of difficulty in existing plants.

There are several good reasons, the first of which is probably that some cushioning effect has been placed in most operating cylinders, which for low or medium heads will effectively prevent the difficulty due to the extreme maximum pressure rise occurring in $2L/a$ sec. On high-head plants there probably have been several instances where this phenomenon has caused difficulty, but it may have been attributed to a more rapid rate of gate motion than the design valve, rather than to an excess pressure rise caused by a partial closure at the normal rate of travel.

A second reason may be found in the general tendency of the rate of governor movement with respect to time to take a characteristic form such that, while the rate of gate motion during the middle section of the stroke, or in fact throughout most of the stroke, is uniform with respect to time, yet the fractional closures do not occur in direct proportion of the time such as a closure from one-half gate to zero in one-half the time, but may require 60 or 70 per cent of the full-load time for this travel. This becomes more pronounced at the smaller gate openings, and typical characteristics, such as those found in Fig. 12, Curves A or B, are found.

The partial opening of the control valves also has an effect upon the determination of the rate of movement, since for small-load changes the pilot valve of the governor is not necessarily raised its full travel, and hence there is only a partial port opening in the distributing valve which reduces the rate of gate movement proportionately by throttling the flow of oil through the governor. Some governor valves are built with variable-ported construction so that only a small part of the area is open when

the valve is lifted a short distance, and this opening increases both in height and in width with the stroke of the valve. With this sort of arrangement the rate of gate motion is reduced very materially for small movements of the gates and actually works for the safety of the plant as long as the gates were controlled by the governor alone. If for any reason a closure from a partial opening is made by raising the pilot valve manually or by other means, the gates would reach their maximum rate of movement even for the small strokes, and the water conduits would be subject to these pressure-rise conditions in such cases, and hence it is unsafe to rely on this means for guaranteeing the safety of the plant.

The general tendency recently has been to increase the governor time for full-load rejections, so that the pressure rise for this condition is decreased to possibly 25 or 30 per cent above normal,

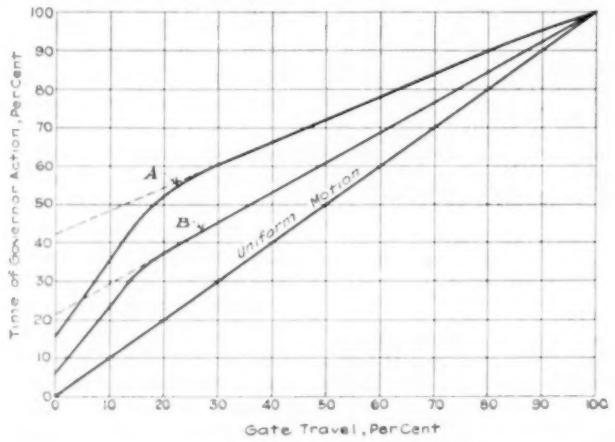

FIG. 12 TYPICAL GOVERNOR TIMING RELATIONS

instead of 50 per cent above normal. In such a case, even the critical pressure rise at some fractional gate opening would not reach greatly in excess of 50 per cent of normal head, and with the factors of safety held within reasonable limits the stress in the pipe line is not excessive.

CONCLUSIONS

Since the pressure rise due to the deceleration of flow in closed conduits is a function of the initial flow from which the deceleration starts, and since the retardation of fractional discharges may prove critical, it is imperative to investigate these conditions to insure the safety of the conduits under consideration.

The true relation of average conduit velocity with respect to gate opening or the opening of the control apparatus is essential for the accurate determination of such critical conditions.

Having once determined this relation, the simple formula of $2LV/gT$ will give the maximum rise in pressure which may occur in the conduit due to some particular closure, providing the motion of the control apparatus with respect to time is uniform and that relation of discharge with respect to gate opening and of gate opening with respect to time is also uniform.

For non-uniform conditions, if the maximum relation of velocity with respect to time can be established, then these two values will enter into this simple formula as a ratio and the true critical pressure rise can be determined in this manner.

For general practice Formulas [3*b*], [4*b*], and [5*b*] may be used but the critical condition will occur when $N = 1$. When $K = 1$ the pressure rise will be given by either Formula [4*b*] or [5*b*] and will correspond to the maximum rise at any point where K is greater than 1 with uniform motion.

The general knowledge in regard to water hammer and the means of correctly computing the maximum rise in pressure by the elastic-wave theory, coupled with the experimental confirmation of the elastic-wave theory, gives assurance to the designer that studies of the water-hammer conditions in accordance with these theories will be the correct basis for the determination of the strength of water conduits. The only concern should be to insure the correct application of these theories and to investigate each phase of the problem.

In the absence, however, of definite determination of the true maximum rise in pressure in accordance with the principles described in this paper, any plant may be in a dangerous condition unknown to the operating personnel.

Discussion

E. B. STROWGER.[12] The author has presented an interesting and useful analysis of the conditions of pressure rise in a hydraulic-turbine penstock for closures from full gate and from partial gate openings. The fact that the pressure rise due to a closure from a partial gate may considerably exceed that for the full gate condition emphasizes the necessity on the part of designers to investigate thoroughly the rise in pressure for the possible critical condition pointed out in the paper.

Recently the writer investigated four problems of water ham-

mer, each case of which showed a critical initial velocity at a partial gate opening which would produce a greater pressure rise than that due to the rejection of full load, assuming of course that both the discharge and the gate opening vary uniformly with respect to time, and also that the duration of closure is proportional to the gate opening. This is shown in Table 2, the last two columns of which give the critical velocity and the pressure rise produced by the destruction of this velocity. In these cases the pressure rise due to the destruction of the critical velocity varies from 109 per cent to 166 per cent of the pressure rise due to the destruction of the full-load velocity. As pointed out in the paper, fractional closures to zero usually occur in a time which is greater

than a direct proportion of the equivalent full gate traversing time, due to cushioning and due to the fact that the opening of the governor-control valve for small-load changes is a fractional value of the full opening. However, if the design is to take care of the contingency of a manual raising of the pilot valve by means of the load-limit device, a safety trip, or any other device capable of manually or automatically raising the pilot valve its full travel, then the pressure rise should be calculated in accordance with the foregoing assumption of a direct proportional duration of closure for the critical partial gate opening.

Table 2 gives a comparison of the time-pressure rise as by Gibson or Quick and the approximate values by the de Sparre-Gariel equations for four examples where $N > 1$ and $K < 1$ and shows a close agreement. Where the de Sparre-Gariel equations apply, their use simplifies the problem materially, as shown in Table 3, which gives both the approximate and the exact solution for a high-head, long penstock job with no surge tank, but with a slow-closing valve designed to close in 40 sec. The nomenclature used is that of Quick.

However, of five water-hammer problems recently investigated by the writer, for three of them the de Sparre-Gariel approximations could not be used, because the rise of pressure was greater than $H_0/2$. This condition is common with low-head plants, so that in these cases the arithmetic integration method, the method of Allievi, or the method of Quick must be used. As in the case of all approximate formulas, each problem must be investigated first to see if it is within the range of application of the approximate formula in question. Failing to do this may result in serious consequences so far as the penstock design is concerned, and for this reason the use of approximate formulas for water hammer is always hazardous in the hands of anybody but those of an expert.

The author does not specify how the gate opening of the turbine should be measured, but it is probably generally understood that the gate opening should be measured in percentage of maximum guide-vane opening and not in percentage of piston stroke of the regulating cylinder. It might be presumed that very little difference exists between the relation of discharge and guide-vane opening and that of discharge and percentage of piston stroke, but there may be considerable difference between the values of pressure rise determined by considering each of these relations. Fig. 13 gives the gate-opening-discharge curve of a 70,000-hp. unit as determined by the Gibson method of testing. Both the piston stroke of the regulating cylinder and the guide-vane opening measured at the vanes are plotted against the values of discharge. The tangents to the curves as shown will of course produce different values of the pressure rise. It will be noted that the guide-vane-opening relation produces a considerably greater rate of destruction of velocity near the end of the closure, and therefore in this case proves to be the more severe so far as pressure rise is concerned. In this particular case the type of operating gear used probably accounts for the wide difference between the curves. This illustration serves to show that, for a very accurate determination of pressure rise, accurate data concerning the turbine performance are necessary.

A Gibson test made on a 37,500-hp. unit produced the diagram of pressure and time as shown by the curve marked *A* in Fig. 14, in which the diagram has been replotted on a horizontal base line. Along with the diagram the chart of gate travel was taken by a recording device mounted on the regulating cylinder. Knowing

the quantity of water flowing in the penstock as determined by the Gibson diagram for the gate opening of the test run, and knowing the rate of gate travel, the pressure-time diagram marked *B* was calculated and compared with the Gibson diagram as to impulse area. The agreement was within $1^1/_2$ per cent, which was very close for the computation, which involved 93.5 intervals or 93 individual computations of pressure rise by the arithmetic-integration process and which neglected friction in the conduit. Another computation was made of the pressure-time diagram using a value for *a* equal to 10 per cent of the former value, e.g.,

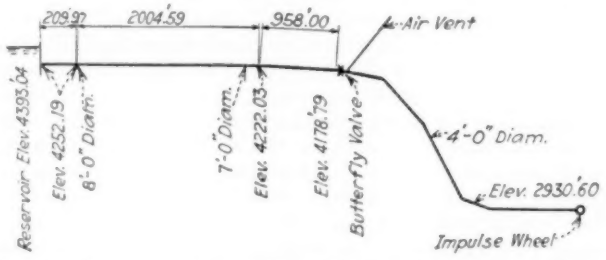

FIG. 15 PROFILE OF HYDRAULIC POWER PLANT WITH VALVE LOCATED ABOUT MIDWAY BETWEEN FOREBAY AND POWER HOUSE
(Control of flow assumed by valve after 67 per cent of its stroke is effected.)

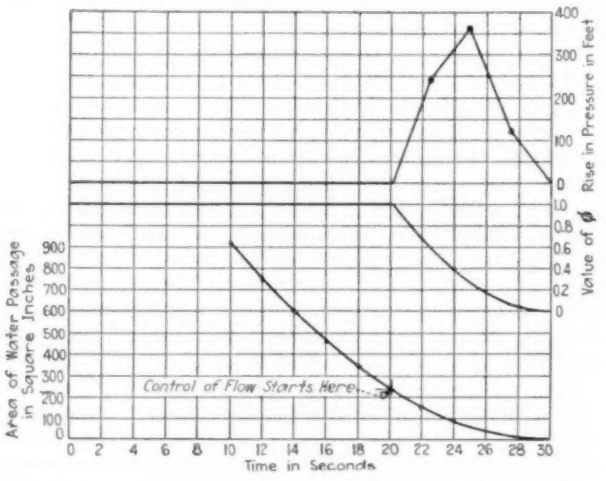

FIG. 16 RELATION OF GATE OPENING AND TIME AND OF PRESSURE RISE AND TIME FOR EXAMPLE OF FIG. 15

$a = 452$ instead of $a = 4520$, with the result that the area remained the same, but the maximum pressure rise increased by 23 per cent. This is shown by the curve *C* in Fig. 14. The Gibson diagram of course measures the impulse due to the closure, but does not necessarily give the correct pressure rise at any given instant. The agreement in area, however, is an indication of the accuracy of the calculation of the actual pressure-rise curve and is given for this purpose. The change in shape of the curve due to a large change in *a* is not great, so that if *a* is determined within reasonably close limits, an accurate determination is obtained in most cases.

Referring to waterworks service, the author states that "in controlling the flow in such a conduit by means of a valve, the discharge is not appreciably affected by the closure of the valve until the area is reduced considerably and the actual loss through the valve assumes fair proportions." The writer recently made an investigation of a water-power plant where this condition existed. Referring to Fig. 15, a butterfly valve was located about midway between the forebay and the impulse wheel. The valve operated under a head of about 215 ft. and the impulse wheel under 1400 ft. The discharge, which was to effect an automatic closure of the valve in 30 sec., was 236 c.f.s., this being 50 per cent greater than the discharge of the wheel at full gate. Under these conditions the valve will be closed to about one-third of its full opening before it assumes control of the flow, and if the full stroke is fixed at 30 sec., the flow will be shut off in about 10 sec., which results in an equivalent traversing time of about $7^1/_2$ sec. Fig. 16 shows the relation between time and the orifice or valve area which is denoted by ϕ. The maximum pressure rise of 361 ft., shown also in Fig. 16, results instead of a rise of 69.9 ft., which is based upon a complete destruction of velocity in 30 sec.

RAY S. QUICK.[13] The striking analysis by Mr. Kerr, showing that the maximum rise in pressure with uniform gate motion may be reached with closure starting from some partial opening rather than full opening, obviously is an important point to bear in mind in the consideration of practical hydroelectric water-hammer problems. While the general variations of the maximum pressure rise may be determined readily by use of the water-hammer charts now available, the limits are not apparent until considered in the light of Mr. Kerr's studies.

A direct confirmation of Mr. Kerr's conclusions for the case of a given head and uniform gate motion may be obtained by reference to Allievi's chart, Fig. 24,[14] by laying a straightedge along the lines of constant pressure rise and noting that they are practically radial through the origin for the major portion of the area of the chart. With uniform gate travel, it is obvious that so long as the line of constant pressure rise is truly radial the rise remains constant, since the initial gate opening and time are changed proportionally. As the origin of the chart is approached, the lines of constant pressure rise dip slightly below the radial, thus indicating that the percentage pressure rise with uniform motion is increasing until closure takes place in exactly one interval, after which the maximum rise reduces uniformly to zero.

In the upper left-hand part of the chart the lines of constant pressure rise reverse in inclination with respect to radial lines, indicating that maximum pressure rise is reached for closure from full gate opening, but this occurs under conditions where the rise in pressure is so many times the initial head that it would not likely be met with in actual practice.

In the region of the Allievi chart where the lines of constant pressure rise are radial, it is obvious that a slight error in the determination of the velocity of the pressure wave *a* is of no consequence, since this factor appears directly in both axes of the chart. Thus, fortunately, one may assume any reasonable value of *a* in a given problem and obtain the same answer for the rise in pressure in this region of the chart. Conversely, for a given allowable pressure rise, the time of gate closure may be established with the same degree of accuracy. However, when working in a region of the chart where the pipeline constant "rho" is less than unity, the lines of constant pressure rise diverge materially from the straight radial direction, thus introducing the possibility of some error for offhand values of *a*. As this embraces the region of high-head plants, care should be taken for such calculations and the true value of *a* closely estimated.

Consideration of the distribution of water-hammer stresses along the pipeline profile is important to bear in mind as it may be found that the factor of safety is a minimum at some point considerably upstream from the discharge orifice. In fact, a review of actual conduit failures in service would appear to bear this out. As the penstock usually dips steeply toward the power house in the lower portion of its length, special care should be taken to

[13] Executive Engineer, Pelton Water Wheel Company, San Francisco, Calif. Assoc-Mem. A.S.M.E.

[14] "Theory of Water Hammer," L. Allievi, translated by E. E. Halmos, 1925.

safeguard this section, as a protection to the power house.

In conclusion, water-hammer stresses should be investigated and provided for not only at the discharge orifice or gate but along the conduit as well. The gate-operating mechanism and governor should be provided with adequate adjustments and safeguards of a "foolproof" nature so that the many modifying factors of practical operation may be allowed for. The addition of a governor-operated relief valve or bypass many times solves a perplexing practical operating problem in combined pressure and speed regulation of hydroelectric equipment. Experience shows that conservatism rather than economy should govern in the selection and arrangement of the plant equipment and penstocks.

EUGENE E. HALMOS.[15] Mr. Kerr has written on this subject before, and I consider this paper to be a sequel to his papers of 1924 and 1926. During the last ten or twelve years much has been written and published on water hammer. However, since Lorenzo Allievi's book one would have thought that there was nothing more to be said about this phenomenon. But Mr. Kerr has managed to find a new viewpoint, something that is worth while to bring before the profession.

Mr. Kerr brings out the fact that it is not sufficient to investigate and design a pipe line for the condition of closing the gate from full opening to zero in a specified minimum time, but it is extremely important that closures beginning at part-gate be studied.

One paragraph from Allievi's book has some reference to this matter. On page 17 he says: "It should be observed, moreover, that of the five elements which characterize a conduit under pressure, the first three, i.e., V_o, a, L, are constructive and in general invariable, whereas V_o and t are functional and are frequently modified, varying the flow of the pipe and the speed of the operation. By such modification of either of these two latter elements the pipe becomes a new conduit in which the phenomena of water hammer may present entirely different laws from those applying when the original assumptions are considered." This calls the designer's attention to the very danger pointed out by Mr. Kerr. We ought to be thankful that he has shown in a forceful manner the danger which may come by neglecting to investigate a pipe line for partial closure and has described the ingenious method by which such study may be carried out.

I do not quite agree with the author's recommendation of using de Sparre's formulas—first, because they are limited in application, as he has stated, and, second, because within that limit they are not accurate.

If in Table 1 the results of de Sparre's formula are compared with those of Gibson, which are derived by arithmetical integration, it will be found that even within these limits there are points where the results are almost 5 per cent off.

The author says this: "The charts of Allievi and Quick offer a more rapid and convenient method of solution and give the maximum pressure rise for any given condition. They have some limitations, however, due to the fact that they are not available universally and, when reproduced in publications, cannot usually be read with great accuracy. This is particularly true of the Allievi chart for conditions involving fairly rapid closures from small gate openings, a serious inconvenience in determining the critical conditions for the problem now under consideration."

I had the privilege of translating this work of Allievi's, and the book has been given gratis to the profession through the generosity of the owner. Anyone applying to the secretary of the several societies can obtain copies of his book.

It is true that in some of the handbooks which reprinted Allievi's chart, the chart which Allievi calls "General Synopsis" has been given. On this chart in the upper left-hand corner there is a blank space where the lines coming close together would make the diagram illegible.

With reference to this diagram I agree with Mr. Kerr that it is really hard to pick an accurate point; but Allievi, for the purpose of eliminating this defect, included another diagram, Fig. 23 in the book, in which he shows this region on such a large scale that there is really no difficulty at all to pick the necessary point with an accuracy which is almost as close as the arithmetical integration and certainly should not vary more than 1 per cent.

BYRON E. WHITE.[16] This paper is of outstanding importance and interest in the field of hydraulic engineering, and is particularly important to those engaged in the design and operation of hydroelectric power plants, especially where long closed conduits are involved. The principles brought out have a most important bearing on the speed or frequency regulation of hydraulic-turbine generating units.

The maintenance of very close speed regulation is most important, especially in textile industries, and is difficult to maintain with hydraulic-turbine equipment, no matter how sensitive the governors may be. It is usual to find considerable wavering of the line of recording frequency meters, when the governing is done exclusively by hydraulic-turbine governors. We have known in general the reasons why frequency fluctuations occurred, but the paper brings out and emphasizes some of these reasons still more strongly.

The importance of the modified gate-opening curve and the mechanism for bringing it about, as described partly by Mr. Kerr and partly by Mr. William Monroe White, ought to be forcibly brought to the attention of all who are interested in the governing of hydroelectric plants. This paper is an evidence that very important progress has been made in the art of so regulating and limiting pressure rises that we may have the pressures in our conduits limited to safe values and at the same time obtain reasonable speed regulation. Some of the overspeed that we sometimes experience is fully as much due to excessive pressure rise as it is to the volume of water which would normally pass through between the guide vanes of the turbine under normal pressure rise in the conduit.

ROBERT E. B. SHARP.[17] I should like to stress the importance of determining the value of a in wood-stave pipe lines. There is very little information on this subject, but what information is available shows that there is a wide variation in values of a that have been determined experimentally. This is only natural when the construction of wood-stave pipe lines is considered, and it is reasonable to expect that this value of a will depend upon a number of variable factors, such as the relation between thickness of staves and diameter of pipe, relation between spacing and diameter of bands and diameter of pipe, wood used in staves, and age of pipe line.

It would be reasonable to expect that this value of a would be lower for a new line than after it has aged and some compression has taken place in the staves and in the degree in which the staves have embedded themselves in the bands. Where the pipe line between the forebay and the hydraulic turbine is made up, as is sometimes the case, partly of a wood-stave section and partly of a steel section, it is essential that some data be available relative to the rate of travel of the pressure wave a of the wood-stave portion of the line in determining the fastest allowable rate of gate movement. Where a water-saving relief valve is installed, as is sometimes the case, the importance of taking into

[15] Parsons, Klapp, Brinckerhoff and Douglas, New York, N. Y.

[16] General Engineer, Utica Gas and Electric Co., Utica, N. Y. Mem. A.S.M.E.

[17] Chief Engineer, I. P. Morris Corporation, Philadelphia, Pa. Mem. A.S.M.E.

account the true value of a is greater for gate openings than for gate closings.

Where a differential surge tank is employed between a wood-stave flow line and the turbine penstocks, the value of a may be so much lower than that assumed in the design and the length of the wood-stave pipe line so great that when loads are rejected from the turbines the ensuing rise of the water level in the riser of the tank may be sufficient to slow down the flow in the wood-stave pipe line such that $T<2L/a$. This results in a pressure rise in the flow line equal to AV/G, which may be destructive.

In view of the foregoing, a systematic effort to determine experimentally the value of a in large numbers of wood-stave lines and the collection of all existing data would be of real value.

Mason A. Stone.[18] The previous discusser has raised the question which I was about to ask as to the value of a, the velocity of pressure-wave propagation in wood-stave pipe. After a careful search through the literature of the subject I find only meager references.

In the latest handbook I found a statement that the velocity of the wave in wood-stave pipe is not predictable, which was most discouraging. A footnote referred to a paper presented before the A.S.C.E. in 1898 by Mark, Wing, and Hoskins. But that was before the correct theory of water hammer has been developed in the paper of Allievi; and while they made some experimental determinations of the pressure in wood-stave pipe lines, they begged the question of the velocity of propagation by saying that is was probably about the velocity of sound in water, which is of course quite wrong, as the elasticity of the staves greatly modifies this value.

There was also a paper presented before this Society in 1912 in which the author substituted the modulus of elasticity of wood for that of steel in a formula for a and laboriously tabulated the values obtained thereby for a wide range of pipe sizes.

Mr. Minton F. Warren criticized this formula in a paper before the A.S.C.E., suggesting its modification by the inclusion therein of an expression for the action of the steel bands. While it is rather late to be discussing a paper presented in 1912, it may be as well to point out that the elastic action of a circle of staves in which the material is not continuous is quite different from that of a continuous steel shell, especially for increased pressure in the pipe, and that therefore the values in this paper obtained by the use of E for wood are probably far from correct.

For instance, Yule's formula for a as modified by Warren gave me a value of about 3800 ft. per sec. for a 72-in. diameter wood-stave pipe. I am under the impression that this is very much too large for a wood-stave pipe and hope that some of the more experienced members may enlighten us on what values we should use for a.

It is very important that we should know them and that we should not be content with the statement that a is not predictable. The author has shown the importance of the water-hammer phenomena which depend directly on its value, and we should certainly be able to apply the results of his paper to wood-stave pipe, as this appears to be the most economical form of long, high-level conduit.

Elmer G. Hooper.[19] Attention has been called to an apparent discrepancy between actual water-hammer pressures and velocities in wood-stave pipes and the theoretical values obtained from accepted formulas. The explanation is that not all the factors influencing energy absorption in this type of conduit have been included in the formulas.

Water hammer, so-called, is the result of conversion of kinetic energy in a moving mass of water in potential energy. It may be expressed as the product of a force times a distance, $P \times D$, where P is one-half the product of the water-hammer pressure per unit area and the area of pipe cross-section and D is the *total movement* of the *mass center* of the water body while under the influence of this pressure. Since the amount of energy absorbed, or converted, in changing the velocity of a mass of water a given amount is constant, $P \times D$ is constant; hence anything that will change D will change P reciprocally. A conduit with comparatively "springy" or "stretchy" walls will develop a correspondingly large value of D with a proportionate reduction in P and in the unit pressure. The velocity of pressure wave is also a function of the "springiness" of the pipe, as is demonstrated in the development of Joukovsky's formula. The mathematical determination of "springiness" in a wood-stave pipe is somewhat more complex than for pipes with walls of simple homogeneous construction like cast iron and possibly steel pipe; Joukovsky's formula deals only with the latter. It is conceivable that this formula can be modified to include the other factors influencing the "stretch" of the pipe walls, though not without considerable study. The important factors are compression of water, compression of wood staves, stretch of bands, and deflection of staves between bands, the last two being influenced directly by dimensions of the units and the spacing of the bands. Such a formula would hold only up to the point where staves would separate and permit water to escape.

In the light of what has been said in the foregoing, the low excess pressures and low-pressure wave velocity in the wood-stave pipe as compared with the values computed from the formula are not difficult to understand.

Samuel Shulits.[20] The statement of the paradoxical fact that the maximum pressure rise due to a load rejection to zero load in a finite time greater than zero actually does not occur with maximum penstock velocity or maximum discharge, as so ably presented by Mr. Kerr, is to many engineers a "contradictio in adjecto;" and this latter truth has indicated the need of an intuitive perception of this interesting phenomenon. The fact of this pressure-rise phenomenon is mathematically so easily perceptible, but descriptively not always obvious. In line with this thought, the writer presents here a physical interpretation of the occurrence.

The purpose of a physical interpretation is in general to so illuminate a mathematical proof or an experimental observation that initial incredulous surprise is raised to an understanding, an intuition, or feeling that the described phenomenon can happen.

Physical Interpretation

With the first closing motion (or jerk) of the gate, the pressure would increase a certain amount due to the destruction of velocity according to the momentum law, under the ideal conditions that the rate of retardation of flow is proportional to the rate of diminution of gate opening and that water and penstock are rigid, inelastic bodies. Since these conditions are not nature-true, the ideal pressure rise does not occur. In its place a smaller pressure rise is realized because a diminution of the rate of retardation of the flow and a deformation of the elastic water and elastic penstock actually do take place.

This diminution of the rate of retardation of the flow suggests the use of a conception of a "relative acceleration." It is well known that the rise of pressure, which commences immediately

[18] Engineer, E. L. Phillips & Co., New York, N. Y. Mem. A.S.M.E.

[19] New York University, New York, N. Y.

[20] Freeman Traveling Fellow of the Boston Society of Civil Engineers at the Prussian Experimental Institution for Hydraulic Engineering and Shipbuilding, Berlin, Germany.

after the gates begin to move, increases the velocity of discharge through the gate opening. With no pressure rise, the velocity at the end of the first gate motion would be smaller than it is with the pressure rise. The difference between these two velocities divided by the time of this first-minute gate motion is a quotient that represents the "relative acceleration" due to increased pressure. This term will be used in this sense hereinafter. It should not be forgotten that the flow is being constantly decelerated during the closure, though at a smaller rate due to the relative acceleration.

Gate closure causes a change of kinetic energy into potential energy. If, during the closure, the total potential energy produced were in some manner during this closure reconverted into kinetic energy, then no pressure rise would be realized. With no such reconversion of energy, maximum pressure rise would result. (The elasticity of the water and penstock is here temporarily neglected for the immediate purpose of the analysis in this paragraph.) A partial reconversion would produce an intermediate value of the pressure rise. The latter is the case in question. The increased head due to the pressure rise causes a relative acceleration of the water to a velocity greater than that corresponding under normal conditions to the opening attained at the end of the small motion under consideration. Thus a part of the kinetic energy liberated and changed into potential energy by the gate closure is reconverted into kinetic energy during the closure.

For the foregoing process of relative acceleration, not all the kinetic energy initially available under normal conditions is needed. The remainder as converted into potential energy by the closure continues in this form and is stored by compression in the water and by expansion in the penstock wall.

It is essential at this point to consider the inertia of the water and the penstock. The column or body affected by the pressure rise is really the totality consisting of a mass of water and a surrounding container penstock. The moving mass of water acts to maintain its velocity against the stoppage compelled by the gate closure. This may be conveniently termed the inertia of the kinetic energy of the column. The water and penstock wall act to prevent the motion of deformation or to maintain their original shape as governed by the stresses in them. The shape and stresses depend on the amount of potential energy initially stored in the water and penstock under normal conditions. We may therefore conveniently speak of the inertia of the potential energy of the column. In the presence of both forms of energy, a predominance of either form of energy means a predominance of the interia of that form and a consequent predominant innate sluggishness toward a change to the other subordinate form of energy.

In the respective magnitudes of these two forms of energy, kinetic and potential, and especially in their mutual relationship, we have a measure of the actual pressure rise attainable. Since kinetic energy involves time and potential energy does not, it becomes immediately evident that the time, too, influences the pressure rise; for the kinetic and potential energy in the column together determine the pressure rise. In other words, the time influences the rate of change of kinetic energy into potential energy, or the *pressure rise*. This conception of the pressure rise as a rate is recognizable in the momentum law:

$$F\ (\Delta T) = M\ (\Delta V)$$

where F = the decelerating force
ΔV = the decrement of velocity
M = the mass
ΔT = an interval of time.

The pressure rise is the force F. The time influence is shown in the time of closure T or in N. This is self-evident.

What is a measure of the attainable rate of energy transformation? How can we measure the inertia influence? What can we use as a yardstick? Simply enough, the answer[21] is the constant K.

$$K = {}^1/_2 \sqrt{\frac{KE}{PE}} = \frac{aV_o}{2gH_o}$$

where KE and PE are respectively the kinetic energy and the potential energy contained by the conduit per unit length under the initial normal steady conditions of flow or with V_o and H_o, as defined by Mr. Kerr. In words, K is equal to one-half the square root of the ratio of the kinetic energy to the potential energy initially present in each unit length of the conduit. For the purpose of this discussion we will use the transposed form of this relation:

$$PE = \frac{KE}{4K^2}$$

Thus, the potential energy present at the start of gate closure varies inversely as the square of K, often called the "pipe-line constant." Between the kinetic and potential energy, then, there is always a natural balance, under the initial normal conditions, as formulated in the foregoing equation.

Greater values of K at larger gate openings are consequently intimately bound with a contained potential energy proportionately small in comparison with the contained kinetic energy, and vice versa. Another view is that with large K the weight is on the kinetic energy side of the balance, while with small K the weight is on the potential energy side. Consequently, with large K greater proportional relative accelerations occur, while with small K greater proportional storage of energy in the water and walls occur. The shorter the time of closure with small K, the greater the rate of energy transformation or storage in order to transform and store the same amount of energy, and therefore the greater the pressure rise.

The foregoing is the nucleus of the writer's interpretation, which will now be applied in illustrating the phenomenon presented by Mr. Kerr.

1 With 100 per cent gate opening and maximum K, we have present the minimum potential energy and the maximum kinetic energy in their proportional relation, together with the maximum time of closure. Of the available kinetic energy with its proportional preponderance and its obstinacy of inertia, a greater part insists on a relative acceleration of the water instead of decorously becoming potential energy immediately. Only a smaller part, then, of the kinetic energy is immediately transformed into potential energy. Now, because we have a larger time for this energy transformation during the time of closure, the result is a smaller rate of transformation of kinetic energy into potential energy. This means a smaller rate of storage of energy in the water and penstock wall or a *smaller pressure rise*, even though a greater proportional amount of kinetic energy is being converted into potential energy.

2 With a small gate opening—say, 10 per cent, to take Mr. Kerr's case—the conditions are proportionately small kinetic energy, proportionately large potential energy, and a short time of closure with small K. Only a smaller part of the available kinetic energy with its proportional subordination is free to accomplish a relative acceleration of the water. The proportional preponderance of the potential energy compellingly aids in these circumstances the net deceleration of the flow. A greater part of the kinetic energy is then transformed into potential energy.

[21] For derivation see "Theory of Water Hammer," Lorenzo Allievi, translated by Eugene E. Halmos, under auspices of A.S.M.E. and A.S.C.E., pp. 8 and 9.

Now, because we have a smaller time for the energy transformation during the time of closure, the result is a larger rate of transformation of kinetic energy into potential energy. This means a larger rate of storage of energy in the water and the penstock wall or a *larger pressure rise*, even though a smaller proportional amount of kinetic energy is being converted into potential energy.

Summary of 1 and 2. Therefore a maximum pressure rise at a smaller discharge than full discharge is possible in a finite time of closure smaller than the finite time of closure of full discharge. The mathematical and physical laws between the conditions of full discharge and those at a smaller discharge are shown by Gariel and de Sparre.

3 The basic relation $PE = \frac{KE}{4K^2}$ permits another conclusion. It states that with very small values of KE and K, PE approaches infinity, also that at zero gate the function is indeterminate. We know quite well the potential energy of our column of water at rest. It is certainly not infinite. It is also true that, with zero-gate opening closed in zero time, there is no pressure rise. Hence it follows from this consideration and from 1 and 2 that the rate of energy transformation or the *pressure rise* reaches a maximum at some gate opening greater than zero and smaller than 100 per cent and then decreases to zero at zero-gate opening. The possibility of a variation from a maximum value to zero in the region of $K = O$ is thus shown by this interpretive analysis.

4 The shape of the pressure-time curve with $N=3$ in Fig. 6 of Mr. Kerr's paper can also be explained. The initial rate of energy transformation or the initial pressure rise has been so large that the column of water receives a relative acceleration actually large enough to bring a visual relief-valve action into play, with a consequent decrease in pressure. With the decrease of this relief action, the pressure rise increases again. The values of K and N influence the shape of the curve.

The writer hopes to have shown that the phenomenon presented by Mr. Kerr is intuitively comprehensible by all. Many pressure-rise studies tend to bristle with constants, formulas, and mathematical abstrusities flung about the utter disregard of their physical significance. The writer uses the formula $PE = \frac{KE}{4K^2}$, but this is really a simple expression of the total physical state of affairs in any penstock; an expression usually concealed by practical necessity in $K = \frac{aV_o}{2gH_o}$.

General Remarks

It should be noted that the maximum pressure is a function not only of the initial gate opening or flow from which the deceleration starts (as Mr. Kerr summarizes), but also of the time in which this initial flow is decelerated. This is strikingly clear when one remembers that the true possible maximum-pressure rise is with maximum penstock and instantaneous closure; or, in Mr. Kerr's Fig. 4, the ordinate that would be obtained with $a'b'$ extended upward to meet ob' produced.

The Allievi chart for "fairly rapid closures from small gate openings" is actually available in Mr. Halmos's translation in Fig. 23. There values of K and N can be read with ease to 0.025.

The conditions described by Mr. Kerr are not unknown to American engineers who have had to deal with pressure-rise problems. Mr. R. D. Johnson of differential-surge-tank fame and one of the forerunners in American pressure-rise studies says:[22] "The highest possible surge above forebay level following a complete shutdown is not necessarily due to the shutting off of the maximum velocity obtainable, but may occur as a result of throwing off part load at a critical velocity," and also "it does not always follow that higher velocities call for higher surge tanks to catch all the water, for, as will now be demonstrated, there exists . . . a critical velocity which necessitates a higher surge tank than any greater or smaller velocity."

To Professor Dr. Adolph Ludin of the Technische Hochschule in Berlin-Charlottenburg and to Dr. Franz Eisner of the Prussian Experimental Institution for Hydraulic Engineering and Shipbuilding in Berlin, the writer is gratefully indebted for a critical reading of the foregoing and for many valuable suggestions.

Author's Closure

Several important points have been raised in the various discussions, and among them is the question of the effect of water hammer on speed regulation mentioned by Mr. Byron E. White. A careful study of the water-hammer conditions in any plant having an appreciable length of water conduit will show the danger of speeding up the action of the governor beyond the value fixed by conservative design. A further study combining speed regulation with water hammer will show that the speed regulation will be much better with a normal rate of governor action than with the governor speeded up, due to the abrupt form of pressure waves set up with a too rapid action of the turbine gates.

Mr. Quick emphasizes the need for the "foolproof" methods of fixing the gate movement. It is the author's opinion that all the adjusting devices for medium- and high-head plants should be set under the supervision of a competent engineer and then sealed in such a manner that no unauthorized person could tamper with them.

Too great emphasis cannot be laid on the point brought up by Mr. Strowger in regard to the relation of discharge and the rate of travel of the control mechanism. The question is not so much a matter of the stroke of the operating piston, the travel of an indicator, or the angular turn of a set of movable vanes, as it is a problem to find the rate of change of velocity in the water conduit. The rate of change of area of the control orifice and the rate of change, if any, of the coefficient of discharge of the orifice are the essential relations.

The question of the accurate determination of the velocity of the pressure wave for different types of conduits is vital to the accuracy of any water-hammer study in the critical zone where $K < 1$. As Mr. Quick points out, in the other ranges where K is greater than unity, the same accuracy is not required in the value of a, but with high-head plants or with long conduits under low heads, the true value of a is essential.

With steel penstocks not embedded in concrete, the value of a can be calculated with a great degree of accuracy, but when surrounded with concrete, the velocity is probably somewhat higher than for a simple steel conduit, and less than a nondeforming conduit such as a rock tunnel. A concrete-lined tunnel probably has the maximum rate of wave propagation, 4660 ft. per sec., but there apparently are no tests available to prove this assumption.

In the case of low-head conduits, particularly with wood-stave lines, as brought out by Mr. Sharp, Mr. Stone, and Mr. Hopper, the analytic determination of the value of a is not susceptible of an easy solution. The only means of securing reliable data is by test, and there have been only a very few such tests made. The two most reliable tests that have come to the writer's attention are those run at the Searsburg plant of the New England Power Company and at the South Falls plant of the Hydroelectric Power Commission of Ontario.

The conduit at Searsburg is over two miles long, and the head on the conduit is approximately 35 ft. at all points along the length. The diameter is uniform, and the measured value of a was about 600 ft. per sec.

[22] Trans. A.S.C.E., vol. 79 (1915).

At South Falls, however, the conduit is under a gradually increasing head, ranging from about 20 ft. at the top to slightly over 100 ft. at the bottom. The tests give a true weighted mean of the value of a, as the measurements taken were the time required for the wave to travel up the penstock and back again, that is $2L/a$ seconds. A number of runs were made and an average of 1400 ft. per sec. was secured from the most reliable of the measurements. The results indicate a value of about 300 or 400 ft. per sec. at the upper end, and perhaps over 2000 ft. per sec. at the lower end.

In the near future there will be several opportunities to test wood-stave pipe lines, and it is hoped that there will eventually be sufficient data collected to determine the value of a with reasonable accuracy.

In conclusion, the author wishes to include the remarks of Mr. Carroll F. Merriam[23] at the meeting: "It gives me great pleasure to read the following cablegram from M. Maurice Gariel, Directeur Général, Atèliers Neyret-Belier et Piccard-Pictet, Grenoble, France: 'Entirely in agreement with your paper. Letter follows. Best wishes. Gariel.' It gives me a great deal of personal satisfaction in having made the introduction between the author of this paper and M. Gariel which led to the presentation of this valuable material in clear and concise form. I have noticed in my contact with foreign engineers that they take a great interest in the proceedings of American engineering societies and I feel that this interest should be especially appreciated."

HYD-51-4

Dredge-Pump Pressures and Thrust Loads

By JAMES H. POLHEMUS,[1] and JAMES HEALY,[2] PORTLAND, ORE.

The Port of Portland engineering staff, desiring to determine the actual thrust loads and pressures acting on the impeller of a dredge pump, carried on some tests which should be of interest to members of this society.

Pressure gages were installed at controlling points in both the front and back heads of the 2700-b.hp. 30-in. pump of the dredge Clackamas and a series of tests run to determine the effect of varying lengths of pipe line, impeller clearances, and impellers with and without relief holes in the back shroud.

The results of the tests showed clearly:

1 That relief holes in the back of the impeller materially reduced the thrust load and did not reduce the efficiency of the pump to any noticeable degree.

2 That renewable clearance rings and small vanes on the outside of the impeller shrouds are necessary to maintain close clearances and control the thrust loads.

3 While large clearances produce low thrusts, close clearances do not create a prohibitive thrust and are necessary to maintain a high pump efficiency.

4 That the pressures on the front and back shrouds are not the same and are considerably less than the pump discharge pressure.

5 That the whirlpool pressures are not as high as the discharge pressure of the pump, and that the pressures in the lower half of the pump casing are somewhat greater than those in the upper half.

6 That it is not necessary to carry the same pressure on the water service to the pump-shaft seal as is the discharge pressure of the dredge pump.

7 That as might be expected the thrust load increased with the total head.

8 That the thrust load is greater for any given condition when pumping material rather than water.

9 That the thrust loads are less for any given heads with the smaller high-speed pump impeller as compared with larger slow-speed impellers.

DURING the early part of 1928, the Port of Portland ran a series of exhaustive dredge-pump-pressure tests on its modern high-powered Diesel-electric 30-inch dredge *Clackamas*.

This was an ideal dredge on which to carry out such a series of tests; the pump motor had both adjustable speed and power regulation so that it was possible to run these tests at various predetermined speeds and at known powers. The dredge pump also was of the latest and most efficient design for pumping large quantities of material through long pipe lines and against high net terminal lifts as necessitated by the Portland, Ore., work.

James Healy, master mechanic in charge of the upkeep of the Port of Portland's dredging plant, conducted the tests in the field and made the computations. C. V. Bjornvall of the Port of Portland engineering staff also assisted in this work.

Nature of Tests

The pump shell was bored both front and back at various locations and pressure or vacuum gages installed so that pressure and vacuum readings could be taken simultaneously of the pressures within the dredge pump, when operating against various lengths of pipe lines, as well as at various powers. Tests were also conducted with closed-back pump runners and those with relief holes in the back shroud.

The pumping medium was clear water, as it was found that if the tests were run when pumping material, the various gages soon became stopped up. At first some tests were made pumping through actual pipe lines, but to make the tests more complete and to be able to run them off with a minimum amount of dredge delay, two test nozzles representing two lengths of pipe line were used.

Object of Tests

Desiring to install ball-bearing or Kingsbury thrust bearings on the Port of Portland dredges, it was necessary to determine as closely as possible the actual thrust loads under various working conditions so as to be able to select the smallest bearing that would amply take care of the maximum thrust loads.

This was particularly important with this type of thrust bearing as its cost increases very materially as the thrust load increases. It is also desirable to keep down the weight and size of such items in modern dredge construction. It was desired to determine what effect various methods of pump design had upon the thrust load and to formulate a set of rules by which the accurate thrust load on any dredge pump could be closely determined.

It is most important that the thrust bearings of the dredge pump not only be large enough to take care of the maximum thrust loads, but also be of simple and rugged design, requiring small maintenance and little, if any, supervision when the dredge is in operation.

The modern pipe-line dredge of today uses 50 per cent more power to drive the dredge pump than was the case a few years ago, likewise the pipe-line pressures are 50 per cent greater, it not being an uncommon practice to operate with pipe-line pressures as great as 110 lb. per sq. in.

We have used both the Kingsbury and the marine horseshoe type of thrust bearings in connection with our dredge-pump developments and our objection to the horseshoe type of thrust bearing, though it is very much cheaper than a Kingsbury thrust bearing, is that it requires too much operating attention; the maintenance expense is high, and it is the cause of many expensive dredge delays. We have never used the SKF ball bearings for dredge-pump work but the U. S. Engineer Department has done so with very good results.

Another object of these tests was to determine accurately what water pressure should be maintained on the main pump-bearing seal. Naturally this problem is greatly simplified if a single-stage centrifugal pump with a large discharge volume at pressures less than 100 lb. per sq. in. can be used.

Description of the Dredge Pump

The 30-in. *Clackamas* dredge pump consists of one cast-steel ring and two cast-steel heads, which form the complete pump.

All the inside surfaces subject to wear are faced with renewable $^3/_4$-in. mild steel plate liners held in place with $^3/_4$-in. countersunk-head bolts.

The whirlpool is concentric with the impeller and is of rectangular section $27^1/_2$ in. between head liners and 8 ft. $10^1/_2$ in. in diameter. The distance between the periphery of the impeller

---

[2] Master Mechanic, The Port of Portland.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., December 3 to 7, 1928, of The American Society of Mechanical Engineers.

to the ring liners is 18 in. The suction is 30 in. in diameter as is the discharge. In designing a new 30-in. pumping unit we probably would use a suction as large as 34 in.; however, in this case we adopted the 30-in. suction to keep all our dredge pumps standard.

The impeller is made of cast steel in one piece and is 70 in. in diameter. To use as much as 3000 hp. on a very long pipe line to build up 110 or 115 lb. pressure would require a runner somewhat larger in diameter, about 72 in. with the present maximum speed. The outer faces of the shrouds are finished to an overall width of 26 in. A ring $^5/_8$ in. thick and 30 in. inside diameter is riveted to the face of the front shroud for the purpose of maintaining a close clearance. This ring is renewed as the clearance is increased by wear.

Outside of this clearance ring and extending to the periphery of the impeller, renewable vane-shaped strips $^5/_8$ in. thick are riveted to the face of the front shroud.

The back shroud is also fitted with renewable vane-shaped strips and relief holes are provided to lessen the pressure on the back shroud and thus reduce the thrust load.

Direction of Thrust Load

The direction of the thrust in a dredge pump is always toward the suction side of the pump. The tests as run did not show any thrust in the other direction under any operating condition and the wear on all of the thrust bearings has shown this thrust to be in but one direction.

When the marine horseshoe type or "collar" type of thrust bearing is used, it is customary to provide equal bearing surfaces in each direction, as practically no extra expense is involved in doing this. On the other hand, with the Kingsbury type of thrust bearing, it would add undue complications and expense to provide for the maximum thrust in both directions.

We have heard it stated at various times by persons who might be expected to know, that a reversal of the thrust load did actually take place. We are quite sure from our practical operating experience, as well as the results of these tests, that if this is so it is of relatively small proportions. It is felt advisable, however, to provide for some thrust load in the opposite direction which assists in maintaining the fixed pump clearances and stops any floating of the pump shaft. With the Kingsbury thrust bearing we specify that the thrust elements have six shoes bearing against the side of the thrust collar toward the pump and two shoes on the opposite side.

Causes of Thrust Load

The thrust load on a dredge pump is caused by three general forces acting on the impeller:

a A force forward (toward the suction side of the pump) caused by the vacuum, built up by the pump, pulling upon that section of the impeller equal to the area within the path of the inner tips of the impeller vanes. A positive force.

b A force forward caused by the pressures inside the pump acting against the back shroud of the impeller. This is also a positive force.

c A force backward or in an opposite direction to forces *a* and *b* caused by the pressures inside the pump acting against the front shroud of the impeller. A negative force.

Methods of Computing the Thrust Load

The method usually used to figure the thrust load on a dredge pump, after assuming a maximum suction head and discharge head, has been as follows:

1 Compute the positive component of the thrust load *a* by multiplying the area of the impeller within the inner tips of the vanes by the suction head. (It is reasonable to assume about a 23-ft. suction head which amounts to approximately 10 lb. per sq. in. or a 20-in. vacuum.) Usually this area is the same as the area of the suction inlet, but in the more modern high-powered pumps this is not the case.

2 Compute the other positive component of the thrust load *b* by multiplying the area of the back shroud by the maximum pressure developed by the pump or the assumed maximum head.

3 Compute the remaining negative component of the thrust load *c* by multiplying the area of the front shroud by the maximum pressure developed by the pump or the assumed maximum head.

It was felt that this method produced a result which was considerably greater than the actual thrust load and that the pressures behind the front and back pump shrouds were not the same as the maximum pressure assumed for the dredge pump, and from previous dredge tests we knew that the pressure in the whirlpool chamber would be less than the discharge pressure of the pump.

With small and low-powered dredge pumps, where the ordinary marine horseshoe type of thrust bearing was used, this was not a serious matter as it only meant the adding of another collar or so. Now, with the more expensive type of thrust bearings, such as the SKF ball-bearing thrust bearing, or the Kingsbury thrust bearing, it is quite a different story when it is important to keep down sizes, weights, and costs.

As a matter of fact, these companies furnishing such thrust bearings for dredge pumps, in computing the total thrust load, assumed certain average pressures as acting on both the front and back head as well as the maximum discharge head and suction head which the dredge pump might be expected to develop.

We had not been able to obtain any real first-hand reliable information as to what these pressures were on the front and back shrouds of the pump impeller and just what factors caused them to vary. We noticed from time to time that various engineers in designing dredge-pump thrust bearings used widely different assumptions for relatively the same dredge pump and pumping conditions.

The thrust load for the *Clackamas* pump was figured by different persons all the way from 48,000 lb. to 160,000 lb. The results of our tests show that the maximum thrust load would be less than 60,000 lb. even with a discharge pressure of 110 lb.

In designing this thrust bearing we played safe and used the old method of not making any allowance for reduced pressures behind the pump impeller shrouds and adopted a maximum thrust load of approximately 100,000 lb. which we knew to be well on the safe side. If we had used a closed-back impeller, the maximum thrust load with 110 lb. pressure would have been considerably more.

Our experience in carrying on various dredge-pump tests, to determine other features of pump design, as well as to test the efficiency of various types of dredge-pump impellers, combined with our actual dredge operating experience, led us to believe that a close method of computing the thrust load of a dredge pump could be determined.

Unknown Variable Thrust-Load Factors

After assuming maximum suction and discharge pressures for the dredge pump, the only unknown factors required to determine the maximum thrust load are the average pressures being exerted on the front and back shrouds of the pump impeller.

We were satisfied that we could find a certain differential in pressures between the front and back shrouds for like diameters and areas. We also knew that we would not find the same pressures in back of the shrouds as in the whirlpool chamber. This shroud pressure was bound to be affected by the following features of the pump design:

1 Clearances between the pump impeller and pump casing, both front and back.

2 Whether the pump impeller was fitted with small vanes outside of the shrouds or not.

3 Whether there were relief holes in the back shroud of the impeller or not.

We have had experience with 20-in., 24-in., 27-in., and 30-in., dredge pumps operating with a maximum pipe-line pressure of 110 lb. and feel safe that this discharge pressure is the maximum to assume for a practical dredge pump. Likewise the adoption of a 23-ft. suction head, which is equivalent to approximately 10 lb. or 20-in. vacuum, is a liberal assumption to make when considering the subject of maximum thrust loads.

Method of Making Pressure Tests

Pressure gages were installed in both front and back heads as near as possible to the top center line and each gage on the front head was directly opposite the corresponding gage of the back head. (See Fig. 1 for the exact location of the gages, their designation, and distance from the center line of the pump shaft.)

To eliminate the pressure error that would be caused by leakage between the liner and the head, hollow countersunk bolts were installed through the liner and head, and gages were connected to the outer ends of these hollow bolts.

Tests were run pumping clear water through an 8-in. nozzle representing approximately 18,000 ft. of pipe line and through a 16-in. nozzle equivalent to approximately 1000 ft. of discharge pipe. The impeller used to make these tests was $^9/_{32}$ in. less in overall width than the distance between heads which allowed for three different clearance settings:

1 With $^1/_{32}$ in. in front and $^8/_{32}$ in. at back
2 With equal clearance front and back, and
3 With $^8/_{32}$ in. front and $^1/_{32}$ in. at back.

Tests at 250, 270, 290, 310, 330, and 350 r.p.m. were run with each clearance setting on the 8-in. nozzle which produced discharge pressures from 42 lb. at low speed to 92 lb. at high speed. We were not able to produce a higher discharge pressure as we could not fully utilize all of the power of the pump motor due to its limitation in speed. However, a large impeller or greater pump speed would utilize all of the power.

Tests at 250, 270, 290, and 300 r.p.m. were run with each clearance setting on the 16-in. nozzle with resulting discharge pressure of 41 lb. at low to 55 lb. at high speed. Simultaneous readings of all pressure gages were taken at each condition of speed, impeller clearance, and nozzle diameter and all properly tabulated. It was not possible to operate at a speed higher than 300 r.p.m. on the 16-in. nozzle because the motor reached its maximum power (2700). In our later 30-in. dredge pump designs, we now provide 3000 b.hp. and use a 72-in. diameter impeller.

In actual dredging practice the pump clearances are checked up once a week. The pump impeller is set with as close clearances both front and back as it is possible to obtain, which will vary from $^1/_{32}$ to $^1/_{16}$ in. Even with an adjustable pump shaft and an adjustable nose ring it may be expected to have clearances both in front and in back as great as $^1/_4$ in. if very sharp and abrasive sand is being pumped through long pipe lines where the pump pressures are high.

Recorded Test-Gage Readings

Tables 1 and 2 give the actual gage readings for each of the tests as conducted as well as the computed thrust loads in each instance. An open-back impeller was used for all runs from 1 to 28 inclusive.

From the actual pressure readings, as given in the tables, any one really interested in the subject of determining dredge-pump thrust loads can compute his own total thrust pressures and draw up a series of curves or formulate a set of laws by which the thrust load of any dredge pump can be accurately determined if it is known what the maximum pump pressure will be as well as the general dimensions and design of the dredge pump.

It is hoped that this paper will bring this subject to the attention of those interested in dredge-pump design and that it will create a free discussion of the subject and result in the greatest advantage being taken of these test records.

Computing Thrust Loads From Test Readings

The pressures as recorded for each condition, *A*, *B*, *C*, *D*, and *Y*, gages were plotted against their respective distances from shaft center and a curve drawn through them.

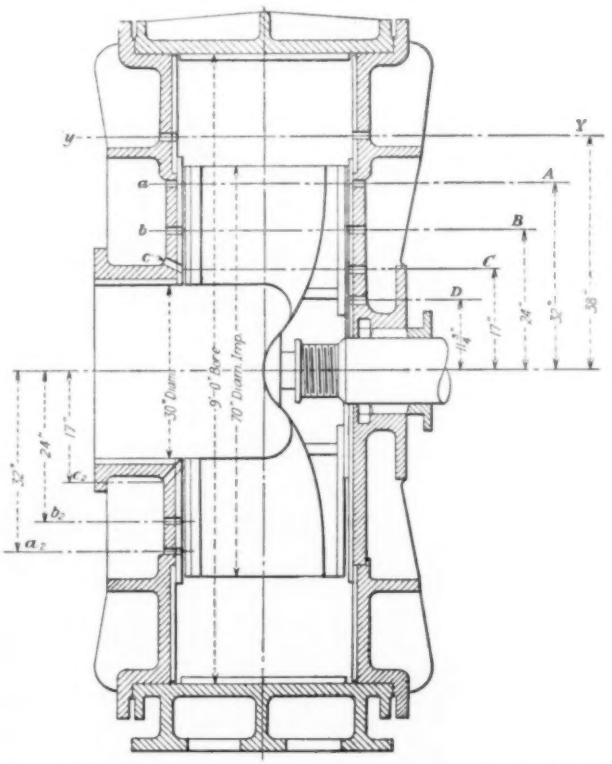

Fig. 1 Cross-Section of Pump Showing Location of Gages

The impeller shroud areas were divided into small area rings of equal width and the pressure as noted on the pressure curve at the radius of the center of width of each area ring was used as the average pressure per square inch for its respective area.

The product of the area and its respective average pressure is the total pressure acting on that area and the sum of the total pressures for all areas on their respective shrouds is the total pressure acting on that shroud. The same method was used for both the front and the back shrouds which make up the two thrust loads *b* and *c*.

The thrust load *a* is caused by the suction vacuum which acts over the area of the impeller whose outer diameter in this case is 30 in. or the path of the inner tip of vanes. The total thrust load is equal to the sum of the two positive thrust loads *a* and *b* minus the negative thrust load *c*.

Fig. 2 shows the method of computing the thrust load in detail for one test or running condition.

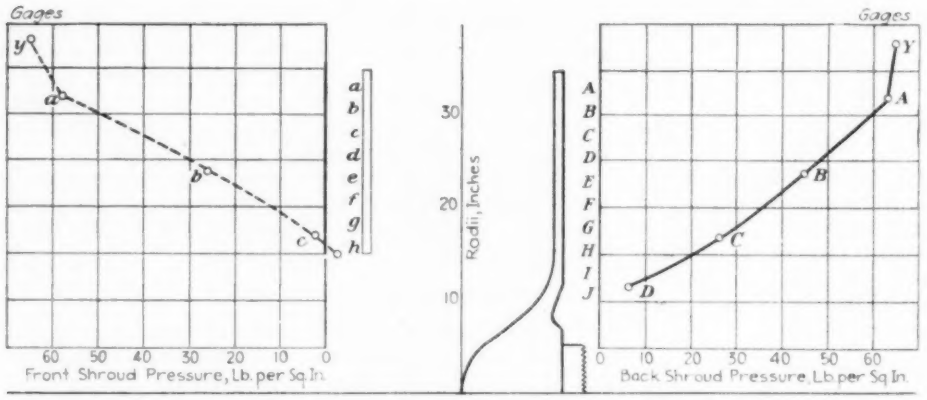

FIG. 2 DETAILED METHOD OF COMPUTING TOTAL THRUST LOAD ON DREDGE PUMP

(Approximate length of pipe line, 18,000 ft.; maximum discharge pressure, 92 lb. per sq. in., vacuum, 5 in.; pumping water)

Pressures	Lb. per sq. in.	Area	Sq. in.	Computations Lb.
A-a	3½	*A*	530	530 × 3½ = 1855
B-b	6½	*B*	490	490 × 6½ = 3185
C-c	11½	*C*	452	452 × 11½ = 5198
D-d	16	*D*	412	412 × 16 = 6592
E-e	19½	*E*	373	373 × 19½ = 7273
F-f	22½	*F*	334	334 × 22½ = 7515
G-g	24½	*G*	295	295 × 24½ = 7227
H-h	24½	*H*	255	255 × 24½ = 6247
I	15½	*I*	216	216 × 15½ = 3348
J	6	*J*	396	396 × 6 = 2376
Vacuum 5 in.	2½	Vacuum	707	707 × 2½ = 1767
				Total thrust load = 52583

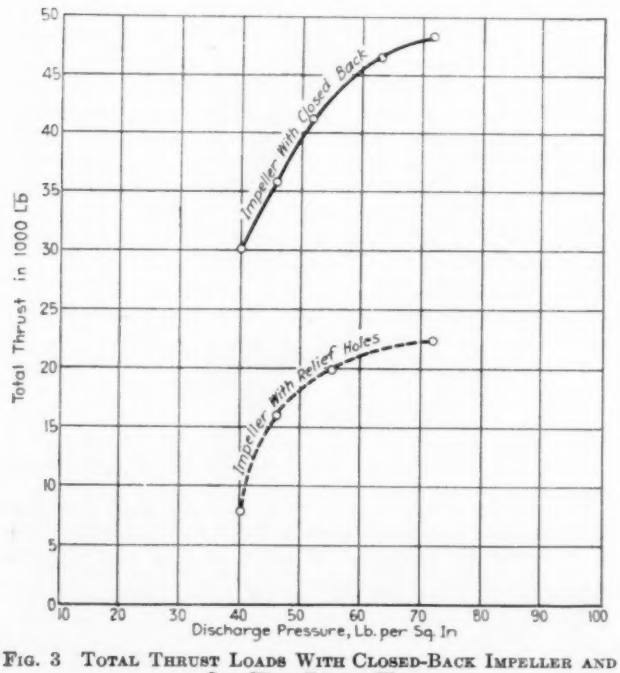

FIG. 3 TOTAL THRUST LOADS WITH CLOSED-BACK IMPELLER AND ONE WITH RELIEF HOLES

(Dredge *Clackamas* tests, Jan. 23, 1928; 70-in. diameter impeller, 3/32-in. clearance front and back; pumping water through 7640 ft. of pipe line with a net terminal lift of 27½ ft.; maximum pressure 72 lb. in both cases.)

EFFECT OF IMPELLER RELIEF HOLES

The *Clackamas* has a heavy marine horseshoe type thrust bearing and it was possible to run comparative dredging tests with both the closed-back type of impeller and the relief-hole type.

As far as dredging results and pump efficiencies were concerned there was no noticeable difference. The impeller with relief holes in the back shroud produced the same pipe-line pressures and vacuums with the same power as did the impeller with these relief holes plugged tight to make it a closed-back impeller. It was quite evident that one impeller would put just as much material through the pump into the fill as the other.

It was demonstrated that the thrust load was less with the relief holes in the impeller and we can see no good reason why relief holes should not be provided in the back shroud of all dredge-pump impellers.

Table 3 gives the actual pressures and computed thrust loads for like tests with the closed-back impeller and one with relief holes in the back shroud. Fig. 3 is a graphic comparison of the resultant total thrust loads.

Relative Pressures Within Pump Casing

As will be noted all the gages were placed on the upper half of the pump as in this location they were easier to read and install. It would be impossible to install these gages on the lower half of the back head. However, to check the assumption that the pressures were relatively the same throughout the pump for any given distance out from the center of the shaft, similar gages were placed on the lower half of the front head and the pressures for these gages were from 2 to 3 lb. more throughout all the tests. (See Table 3.)

For all practical purposes it was felt that the gage readings on the upper half were accurate enough for computing the thrust loads in as close a manner as it would be practical to select or design a thrust bearing. It was felt that the differential in pressures between the front and back heads would remain constant for each relative position of the gages.

By referring to the tabulated pressures taken during these tests, it is clearly shown that the discharge pressure of a dredge pump is higher than the pressure within the whirlpool.

[1] Pumping material.

Fig. 4 shows the thrust load plotted against discharge pressure with the impeller set for a clearance of 1/32 in. in front and 9/32 in. in back. Curve 1 is for the 8-in. nozzle, equivalent to approximately 18,000 ft. of pipe line, and Curve 2 is for the 16-in. nozzle, equivalent to approximately 1000 ft. of discharge pipe.

Fig. 5 shows the same thing except that the impeller clearance is equal both front and back, amounting to 9/64 in. Curve 3 is for the 8-in. nozzle and Curve 4 is for the 16-in. nozzle.

Likewise Fig. 6 shows the same thing but the impeller clearance is 5/32 in. in front and 1/32 in. in the back. Curve 5 is for the 8-in. nozzle and Curve 6 for the 16-in. nozzle. This close clearance in the back is just the reverse from the close clearance in the front as shown by Fig. 4.

A study of these curves shows that it is more important, as far as obtaining low thrust loads is concerned, to have a close clearance in the back rather than a close clearance in the front and a more open clearance in the back. Operating with close clearances both front and back, a high pump efficiency is maintained but not the lowest thrust load. Clearances as close as 1/32 in.

both front and back do not give as low a thrust load as the combination of $^{9}/_{32}$ in. front and $^{1}/_{32}$ in. back. It is obvious that the greater front clearance increases the value of the negative thrust load acting on the front shroud.

It will be noted that the total thrust load on the 8-in. nozzle varied from 10,600 lb. with all the clearance in the front, to 47,600 lb. with all the clearance in the back. With the clearances equal both front and back ($^{9}/_{64}$ in.), we got a total thrust load of 30,400 lb., which is approximately a mean between the two above extreme conditions, as might be expected.

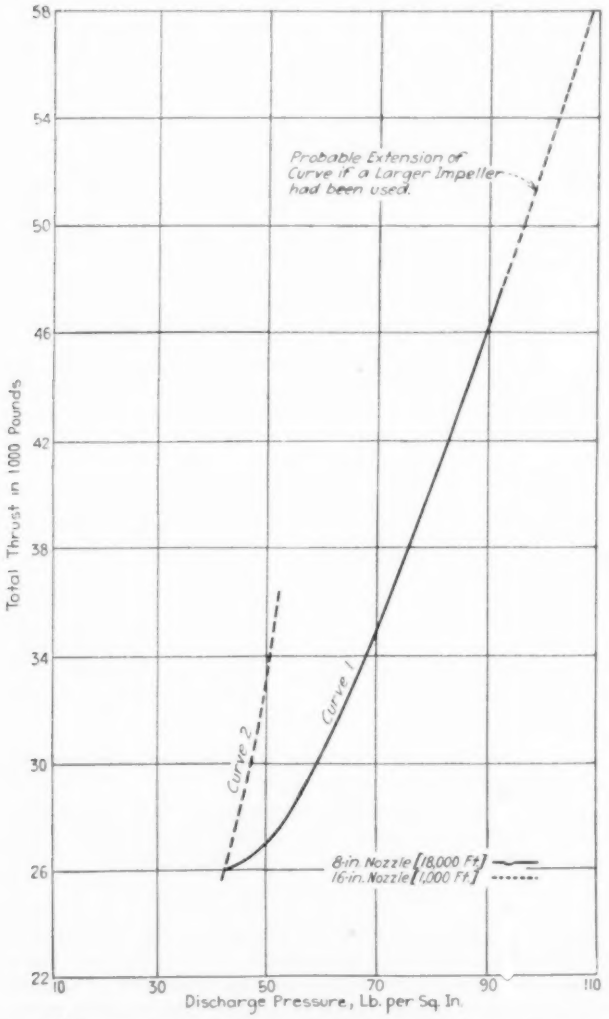

FIG. 4 THRUST-LOAD TESTS, 30-IN. DREDGE *Clackamas*, FEB. 21, 1928

(Front impeller clearance, $^{1}/_{32}$ in.; back impeller clearance $^{9}/_{32}$ in.)

A similar thrust-load relationship between the front and back clearances holds true for the 16-in. nozzle or an equivalent shorter length of discharge pipe line.

EFFECT OF PUMP HORSEPOWER

Fig. 7 shows the thrust load plotted against shaft horsepower for the 8-in. and 16-in. nozzles with both extremes of clearances. Curve 7 is for the 8-in. nozzle and Curve 8 is for the 16-in. nozzle with $^{1}/_{32}$ in. clearance in front and $^{9}/_{32}$ in. clearance in back. Curves 9 and 10 are the same with a front clearance of $^{9}/_{32}$ in. and a back clearance of $^{1}/_{32}$ in.

It is apparent from these curves that the thrust load increases with an increase of pump power for any given condition, due to the fact that the increased power increases both the discharge and suction heads.

EFFECT OF PUMP SPEED

Pump speed has no direct effect on the thrust load. The thrust load is caused by the pressures built up within the pumping casing, therefore, pump speed and horsepower are only incidental to bringing about the resultant pressures.

It is important to bear in mind, however, that the maximum thrust loads occur at top pump speeds which give the thrust bearing its greatest efficiency or capacity. Also high-speed dredge pumps have smaller pump impellers and the thrust load increases materially where it is necessary to increase the diameter of the impeller to raise the discharge or pump pressure.

Fig. 8 shows the relationship between impeller diameters and total thrust loads for the *Clackamas* dredge pump with a 70-in. diameter impeller, developing 92 lb. discharge pressure and a 5-in. vacuum, pumping water. Curve 11 represents the thrust load for

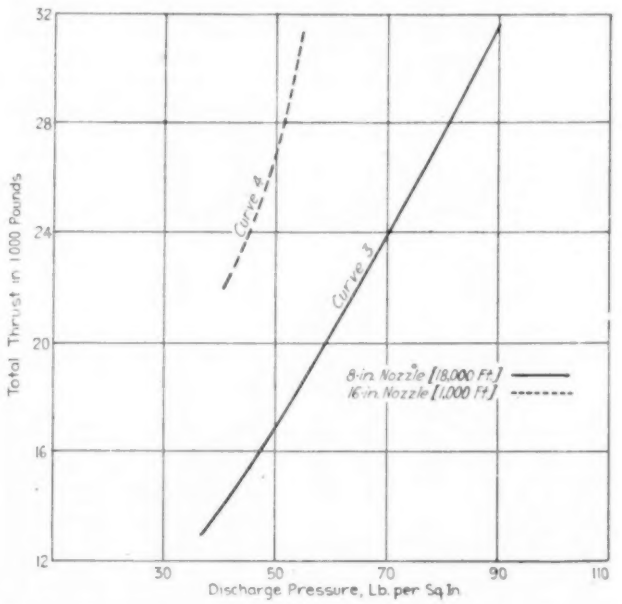

FIG. 5 THRUST-LOAD TESTS, 30-IN. DREDGE *Clackamas*, FEB. 21, 1928

(Front impeller clearance, $^{9}/_{64}$ in.; back impeller clearance, $^{9}/_{64}$ in.)

a $^{1}/_{32}$-in. clearance both front and back as might be expected when the pump was new, and Curve 12 is the thrust load for $^{1}/_{4}$ in. clearances after the clearance rings become badly worn. These curves not only show that the thrust load is considerably greater when large-diameter impellers are used to develop any given head, but also that the thrust loads are less with the $^{1}/_{4}$-in. clearances both front and back than with $^{1}/_{32}$-in. clearances.

EFFECT OF SIZE OF PUMP SUCTION

As the suction vacuum acts upon that part of the impeller within the suction area, any increase or decrease in the size of this area will naturally cause an increase or decrease in thrust load. This increase, however, is not great.

Assuming a maximum suction head of 23 ft., or approximately 10 lb. per sq. in., or 20 in. vacuum, the thrust load from this cause for dredge pumps having various size suctions is as shown in Table 4.

Though these tests pumping clear water did not show a combination of high suction vacuum and high discharge pressures,

TABLE 4 THRUST LOAD DUE TO SUCTION HEAD

Diameter of pump suction, in.	Area of pump suction, sq. in.	Thrust load at 10 lb. per sq. in., lb.
20	314	3,140
22	380	3,800
24	452	4,520
26	531	5,310
28	616	6,160
30	707	7,070
32	804	8,040
34	908	9,080

such a combination is possible in certain classes of dredging and, therefore, should be taken into consideration when determining maximum thrust loads.

Curve 10, 16-in. nozzle, back clearance, 1/32 in.

EFFECT OF LONG PIPE LINES

The effect of pumping through long pipe lines is to increase the thrust load as greater pipe-line pressures are required. This is clearly illustrated by studying the test data of the run on the 8-in. and 16-in. nozzles representing the two extreme conditions of pipe-line length.

It is not uncommon to find pipe-line pressures up to 110 lb. being used on all sizes of dredges from 20 in. up to 30 in. High terminal lifts also increase the pump pressures and as a practical guide in our work, we consider one foot of lift to be equivalent to approximately 100 ft. of 20-in. pipe, 75 ft. of 24-in. pipe, and 50 ft. of 30-in. pipe.

EFFECT OF PUMPING MATERIAL

It was shown that the thrust load was greater when pumping material than when pumping only clear water. This is due to the increased suction and discharge heads when pumping material. Refer to Table 3 giving data of test made on the *Clackamas* on January 23, 1928, to determine the effect of impeller relief holes.

RESULTS OF TESTS

Though these tests were not as scientifically conducted as they might have been, it was felt that they were run quite closely enough for all practical purposes. Likewise the computations were made in a simple manner understandable to the average dredge operator and close enough to determine the maximum thrust load on the dredge pump and show what the influencing factors were for increasing or decreasing the thrust load of a dredge pump.

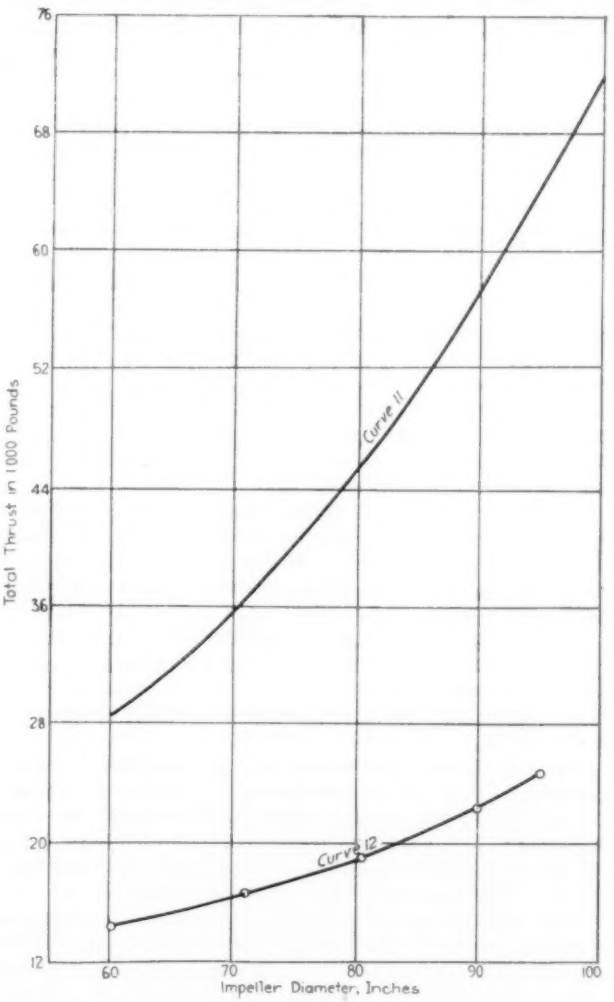

FIG. 8 RELATIONSHIP BETWEEN IMPELLER DIAMETER AND TOTAL THRUST LOAD, DREDGE *Clackamas*, FEB. 21, 1928

(Diameter of impeller for test, 70 in.; size of nozzle, 8 in.; discharge pressure, 92 lb., vacuum 5 in.; pumping clear water. Curve 11, impeller clearance 1/32 in. front and back; Curve 12, impeller clearance 1/4 in. front and back.)

It was clearly shown that a close pump clearance on the back and a more open clearance on the front produced the lowest thrust load for any given condition. However, such running clearances do not permit the obtaining of the best pump efficiencies and it is believed best to operate with close clearances both front and back of the impeller with a slightly increased thrust load.

The closed-back impeller creates a higher thrust load and has no practical advantages over the impeller with relief holes. Impellers with renewable vanes on their shrouds permit the maintenance of closer pump clearances and the carrying of lesser thrust loads. As naturally expected, the longer pipe lines requiring the higher heads produce the maximum thrust loads.

It was also clearly shown that the high-speed dredge pump with a relatively small pump impeller builds up less of a total thrust load than the slow-speed dredge pump with an impeller of larger diameter, all other things being equal. That a 110-lb. discharge pressure and a 23-ft. suction head (approximately 10 lb. or 20 in. vacuum) are reasonable maximum assumptions to assume for a modern high-speed high-powered dredge pump for sizes varying from 20 to 30 in. Although it is possible to set the pump impeller with a clearance of $^1/_{32}$ in. both front and back, it is reasonable to suppose that this clearance will increase as much as $^1/_4$ in. between repair periods but these tests show that this reduces the thrust load. (See Fig. 8.)

It was also demonstrated that relatively low water pressures on the main pump-shaft packing seal are sufficient even with closed-back impellers and high pump discharge pressures.

The practical use of these test data to the Port of Portland has been as follows:

1 It permitted the Port's engineering staff to compute closely the probable maximum thrust loads for all of its high-powered dredge pumps, varying in size from 20 in. to 30 in. and to select the most economical size of bearing.

2 It fully demonstrated the advantages of certain principles of dredge-pump design which the Port's engineers had always advocated, such as relief holes, outside shroud vanes, close clearances, high-speed small impellers, adjustable nose ring, adjustable pump shaft, etc.

3 It made clear to the operating force what can be done to reduce the thrust load, and what operating practices actually affect the thrust load.

4 It determined the proper water pressure to carry on the pump-shaft seal.

The data obtained from these tests permit a competent dredge-pump designer to compute the thrust loads for any given pump. No attempt has been made here to set forth the maximum thrust loads for the various sized dredge pumps in general use throughout the country as each pump is a problem in itself, depending upon its own characteristics and type of design.

These test data should be of value to the various manufacturers of thrust bearings in permitting them to develop a complete line of thrust bearings for dredge pumps to economically take care of all the standard sizes, such as 20-, 22-, 24-, 27-, and 30-in. pumps. Likewise this information should be of service to many of the designers and builders of dredge pumps.

Discussion

R. L. DAUGHERTY.[3] I should prefer to have the title of this paper use the term "centrifugal pump" rather than "dredge pump," because a dredge pump is merely one type or class of centrifugal pump. This changed title would make it clear that the principles and facts here set forth had a broader field of application.

[3] Professor of Mechanical and Hydraulic Engineering, California Institute of Technology, Pasadena, Calif. Mem. A.S.M.E.

What makes a dredge pump different from some other centrifugal pumps is that it is of necessity single suction in practically all cases, and also is usually operated only under relatively high pressures. Furthermore, because of the material it has to handle, certain features of its mechanical construction are naturally somewhat different from pumps handling clear water. But these factors affect the numerical result merely and not the principles involved.

The tests presented in this paper have the advantage of having been made on a pump of large physical dimensions. In measuring pressure distribution on the shrouds of an impeller as large as 70 in. in diameter, there is some gain in accuracy, because the dimensions involved in gage connections are so small in comparison with the impeller dimensions.

The total pressure on any area is given by $\int p dA$ where p is unit pressure and dA is an element of area. The authors have presented curves showing the variation of unit pressure as a function of radius of the impeller, and then used a simple arithmetical method of computing the total pressure. It would seem better to me to plot p as a function of the radius squared. The area bounded by such a curve, when expressed in proper units, is the value of the integral or the value of the total pressure. Furthermore, if the curves for pressure on each shroud are plotted on the same diagram as a function of the radius squared, the area between the two is the net thrust due to these two opposing factors.

There is one force causing thrust that the authors have overlooked, and that is the dynamic force due to the velocity of the water entering the impeller in an axial direction and then being deflected so as to leave in a radial direction. This force is W/gV, where W is pounds of water per second, V is velocity in feet per second in the suction pipe, and g is the acceleration of gravity in similar units. If A is the area of the pipe in square feet, this force is $\frac{62.4 \times A \times V^2}{g}$ and thus increases as the square of the discharge.

In this specific case with a 30-in. suction pipe and velocities ranging up to about 25 ft. per sec., as near as I can estimate from the data given, the thrust due to this dynamic effect reaches a value of 6120 lb. This is hardly negligible. The authors have considered a force due to the vacuum in the eye of the impeller, and in this specific case it had a maximum value of 7070 lb. It is seen that these two forces are of about the same magnitude. They are also opposite in direction, as the dynamic force on the impeller is directed away from the suction side.

In case a pump has a large rate of discharge and thus a large dynamic force acting and at the same time is working under a very low head, thus having a small thrust due to pressures on the shrouds, it might be possible for this dynamic force to be a predominating factor and thus cause the net thrust on the pump to be in the opposite direction from that which it was always found to be in the pump with which this paper is concerned.

By various combinations of clearance rings on both shrouds, and by different clearance distances, it is possible to vary the pressures on the two shrouds also in such a way as to cause a reversal of the net thrust. The authors simply failed to have the proper combination in this case to cause the thrust to be either zero or opposite in direction under some conditions.

In closing, I wish to emphasize the fact that this paper does not present an actual measurement of thrust. The experimental results consist simply of measurements of pressure distribution on the shrouds. The values of thrust given are merely computed values and are correct only if all factors have been allowed for.

I wish to thank the authors for having given to us, however, this valuable study of pressure distribution on the shrouds.

ELTON RISLEY.[4] Vanes on the outside of the runner shrouds add to the wear and tear and decrease the pump efficiency when the clearances get large. Balance holes may not noticeably decrease the efficiency of a 30-in. pump when used in connection with vanes on the outside of the runner shrouds, but would be more serious on a 16-in. pump without such vanes. We have reached the conclusion that the most economical method of taking care of thrust in a dredging pump, when both pump, efficiency, and maintenance are considered, is with an adequate thrust bearing. That is when pump efficiency is expressed in terms of the cost of power-plant installation and operation.

A. L. MCHUGH.[5] The authors have described a method of approximating the thrust on a dredge-type centrifugal pump by measuring the mean pressure at various diameters between the impeller shrouds and the casing and calculating the thrust directly from the values obtained.

The impeller shown is of the enclosed, side-suction type with shallow vanes fitted on outside of shrouds which rotate in the clearance space between impeller and casing and, by means of the forced vortex produced, reduce the pressure from the outer diameter of the impeller toward the shaft to a minimum. As the pressure reduction varies with the clearance between the vane and the side of the casing, it follows that as this clearance is increased the action of the vanes affecting the reduction of the pressure on the sides of the shrouds is materially reduced.

From Table 1, with maximum clearance on the back shroud, the thrust is maximum and is toward the suction. The clearance between the edge of the vanes and the casing is $^1/_4$ in., and the effect of using these vanes is considerably reduced.

The thrust resulting from the mean pressure on the rear shroud is toward the suction. The vanes on the front shroud have but $^1/_{32}$-in. clearance and operate much more efficiently,

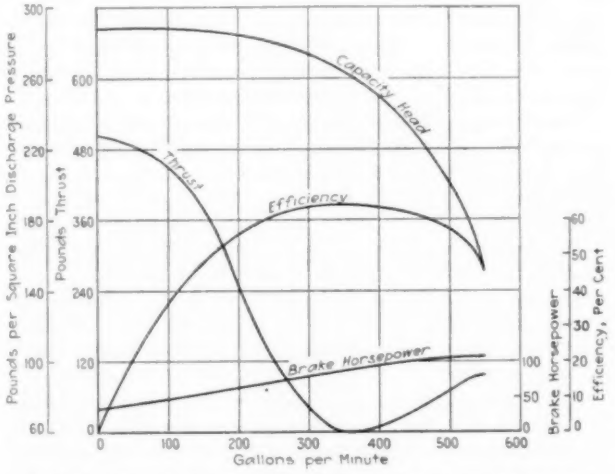

FIG. 9 THRUST CURVE FROM TEST ON A MULTISTAGE PUMP

and consequently the mean pressure back of the vanes is greatly reduced.

As the thrust due to the mean pressure on the front shroud is negative or away from the suction, the net thrust in the direction of the suction is increased in proportion as the amount of the mean pressure at the front shroud is reduced. Obviously, better balance would be effected under these conditions if the vanes were left off the front shroud. Partially balancing the pressure in the clearance space on each side of the impeller by means of holes through the rear shroud should not noticeably affect the efficiency on units of this size and will reduce the thrust materially.

Experimental results made in the laboratory of the company with which the writer is associated indicate that while the thrust may be approximated for points of best efficiency, there is a wide variation in the thrust when the pump is operated under a throttled condition or at a capacity beyond that at maximum efficiency.

The curve shown in Fig. 9 is a thrust curve from actual test on a multistage pump with single side-suction impellers which have balancing rings of the same diameter on each shroud and in which the chamber under the balancing ring from the shroud opposite the suction is connected through the hub by means of balancing ports. At the point of maximum efficiency it will be noted that the thrust is practically zero. As the pump is throttled the thrust increases very rapidly, and on this particular pump it was maximum at shutoff.

In order to measure the thrust a special attachment was built consisting of a pressure chamber covered with a rubber diaphragm on which rests a guided plunger. The thrust from the outer race of the ball bearing was transmitted directly to this plunger, and the pressure in the casing was read by means of a Bourdon gage. In order to build up the proper counterthrust an Alemite gun was used with a heavy oil to produce the proper pressure in the chamber behind the diaphragm. This device was calibrated before using on a platform scale, so that the thrust could be read directly from a curve by taking a reading from the gage.

On a single-purpose pump like a dredge pump, it might pay to mount the thrust bearing in a movable assembly so that the thrust could be read at any time by simply releasing a suitable locking device. If the thrust bearing is mounted on the shaft so it could be adjusted, the impeller could be shifted at times to minimize the thrust due to unequal wear.

The author mentions the fact that he has never used ball thrust bearings on his dredges. Most of the bearing failures in the past have been due to misapplication, and usually they were too small. The published ratings of ball bearings vary, and three of the larger ball-bearing manufacturers are now rating their bearings on a basis of 1000-hr. life. Halving the load, it is estimated the life is increased 10 times, and at one-quarter load the life will be approximately 100 times the full load. After having determined, therefore, the maximum thrust developed by the pump, the selection of the size of the ball bearing is simply a matter of the number of hours the bearing may be expected to operate before replacement.

In the absence of any definite method of measuring the thrust on a pump as large as the dredge pump described in this paper, the writer believes that it would be economy in the end to figure the thrust bearing on a basis of double the estimated thrust in order to insure continuous operation.

VICTOR J. MILKOWSKI.[6] The subject is of importance, not only to designers and operators of dredging pumps, but to designers of centrifugal pumps as well, especially pumps of the side-suction type, as similar reasoning and theory apply to them.

The writer has approached this subject in the course of his work both from a theoretical standpoint and from available test data. It is a pleasure to find in this case that the theory and practice are in accord, except for such discrepancies as are due to imperfections in equipment, etc. The assumptions in

[4] Vice-President and General Manager, Hill Dredging Company, Ventnor, N. J.

[5] Chief Engineer, Goulds Pumps, Seneca Falls, N. Y. Mem. A.S.M.E.

[6] Engineer in Charge of Dredge Department, Morris Machine Works, Baldwinsville, N. Y.

this paper as to the different external forces acting on the impeller and the assumption of the unknown factors affecting these forces are in accordance with the writer's studies and observations.

It will probably be best, first to compare the actual observations with the theoretical figures. The writer will select for this purpose test No. 12 (Fig. 10) with the same clearances on

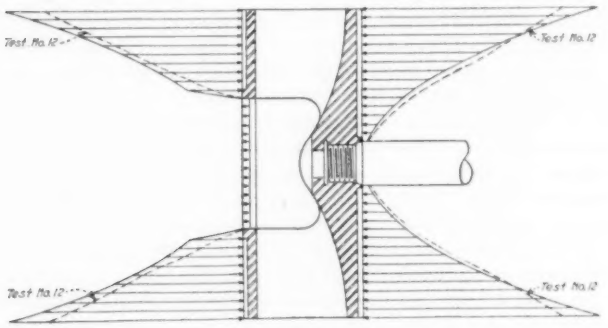

FIG. 10 DIAGRAM OF PRESSURES CAUSING THRUST ON DREDGE-PUMP IMPELLER

both sides of the impeller, no relief holes in the impeller, the pump operating at 350 r.p.m., and discharging through an 8-in. nozzle, the discharge pressure being 90 lb. and the suction vacuum 4 in.

With very close clearances between the impeller and the sides of the pump casing, and with the outside of the impeller shrouds being fitted with ribs or vanes so as to cause the water to rotate with the impeller, that portion of the pump may be considered as being a forced vertex, and the head or pressure at any point as being equal to $H = \frac{V^2}{2g}$, V being the velocity in feet per second and H the head in feet.

This formula can be expressed more conveniently as follows:

$$H = \left(\frac{\text{r.p.m.} \times 2\,\pi\,R}{480 \times 12}\right)^2$$

R being the radius in inches.

The pressures calculated in this manner compare with the actual observed pressures in test No. 12, as shown in Fig. 10 and as given thus:

	Theoretical pressure, lb.	Observed pressure, lb.
Back gages		
A	65	61
B	36	40
C	18	22
D	9	11
Front gages		
a	65	57
b	36	33
c	18	10

These theoretical and observed pressures agree quite closely. The lower pressures observed on the suction, or the front, shroud are undoubtedly due to leakage past the sealing ring at the suction. The higher pressures observed on the back shroud at points B, C, and D may be due to the sealing water supplied to the gland or to larger clearances at that point. A similar agreement is found to exist between the calculated pressures and the observed pressures for other tests as well.

The total head or pressure exerted at any surface is $H \times$ area.

In case of a revolving disk or ring with the variable pressures as mentioned, the total pressure or head can be expressed as an integral of

$$\int_{R_2}^{R_1} \pi\,RH$$

Since from a previous formula $H = \left(\frac{\text{r.p.m.} \times 2\,\pi\,R}{480 \times 12}\right)^2$, the total head equals the integral of

$$= \int_{R_2}^{R_1} 2\pi\,R \left(\frac{\text{r.p.m.} \times 2\pi\,R}{480 \times 12}\right)^2$$

$$= \int_{R_2}^{R_1} 2\pi\,R \left(\frac{\text{r.p.m.}}{916}\right)^2 R^2$$

$$= \int_{R_2}^{R_1} 0.0000075 \times \text{r.p.m.}^2 \times R^3$$

$$= {}^1/_4 \times 0.0000075 \times \text{r.p.m.}^2 \int_{R_2}^{R_1} 4R^3$$

$$= 0.000001875 \times \text{r.p.m.}^2 \times (R_1^4 - R_2^4)$$

In considering the different pressures acting on the outside of the impeller, this theoretical pressure shall be assumed to apply on the front shroud between R-35 and R-17. This, of course, would be in a negative direction, away from the suction. Between R-17 and R-15 it shall be assumed that the pressure changes to a vacuum and that the thrust produced on this ring is negligible. Between R-15 and R-0 the pressure would be uniform and would be equivalent to a vacuum of 4 in., or 5.2 ft. head per square inch. This pressure would be positive; that is, toward the suction.

On the back shroud it shall be assumed that the pressure would be in accordance with the same theory, but would extend from R-35 to R-5. This assumes that the ribs extend all the way down to the shaft and that close clearances are maintained all the way down. This probably is not in accordance with the facts, and any such error will reduce the calculated thrust. This thrust will also be in a positive direction.

The sum of these three thrusts will give the actual thrust to be provided for in the bearing. These assumptions are made more clear by referring to the diagram, Fig. 10.

The negative thrust on the suction shroud will then be $H = 0.000001875 \times 350^2 \times (35^4 - 17^4) = 325{,}500$ ft. $= 141{,}000$ lb.

The positive thrust on the suction due to the vacuum is then equal to $H = 15^2 \times \pi \times 4.52 = 3200$ ft. $= 1385$ lb.

The positive thrust on the back shroud is then equal to $H = 0.000001875 \times 350^2 \times (35^4 - 5^4) = 344{,}800$ ft. $= 149{,}000$ lb.

The total thrust is then the sum of $-141{,}000 + 1385 + 149{,}000$ lb. $= +9385$ lb.

The thrust as actually computed from observations in test No. 12 is 30,400 lb. The discrepancy between the theoretical figure of 9385 lb. and the actual figure of 30,400 lb. is due mainly to the leakage between the suction disk and the front shroud.

Comparing the pressures observed at A, B, and C with those observed at a, b, and c, and which should be the same at corresponding points if clearances were the same on both sides of the impeller and if no appreciable leakage could take place, it is found that there is a positive thrust on that part of the impeller between R-35 and R-17 of approximately 18,500 lb. This leaves only a discrepancy of about 2500 lb. to be accounted for, and this is probably due to larger clearances at the back shroud in the neighborhood of the shaft, lack of vanes at that point, etc. Possession of more details regarding the construction of the impeller and the pump would probably explain these discrepancies.

In figuring the thrust for pumps, the writer figures on a

20-in. vacuum over the suction, the difference between pressure on the front shroud and on the back shroud the same as figured in the foregoing, and on there being an unbalanced pressure of $1^1/_2$ lb. per sq. in. over the whole area of the front shroud, this unbalanced pressure acting in a positive direction. Applying these figures in this particular case gives the following results:

Thrust due to vacuum equals $15^2 \times \pi \times 22.6 = 16{,}000$ ft. $= +6930$ lb.

Pressure on the front shroud equals —141,000 lb.

Pressure on the back shroud equals +149,000 lb.

Unbalanced pressure over the front shroud equals $(35^2 - 17^2) \times \pi \times 1.5 = +4420$ lb.

Adding the foregoing figures, $-141{,}000 + 6930 + 4420 + 149{,}000 = +19{,}350$ lb.

This is the thrust load the writer ordinarily would figure on as the actual working load to be provided for in a pump of this design.

Regarding the possibility of reversal of thrust as mentioned in the paper, it can be seen readily by comparing tests Nos. 6, 12, and 18 with thrust loads of 47,600 lb., 30,400 lb., and 10,700 lb., respectively, that the thrust can easily be reversed by increasing the clearance between the front shroud and the suction disk. In fact, on test No. 18, with the proper sealing arrangement at the impeller intake, there would be a negative thrust of about 8000 lb., if it is assumed that the effect of the leakage is the same as in test No. 12; that is, about 18,500.

Regarding the question of putting relief holes in the back shroud of the impeller, that no doubt would relieve the thrust at that point; and as the vanes on the outside have similar pumping action as the vanes inside of the shrouds, the efficiency of the pump as a whole would not be reduced perceptibly, especially with as large a pump as in this case.

There are, however, practical considerations against this. It introduces wear between the back shroud and the hub disk and permits sand and grit to get into the stuffing box and packing. For these reasons the writer considers it best to eliminate the relief holes from the back shroud entirely.

The writer is tempted to make some observations on the efficiency of this pump. Taking test No. 12 with pump discharging through an 8-in. nozzle at 90 lb. pressure, or 208 ft. head, and assuming the nozzle to be 98 per cent efficient, it is found that $A = 50.27$ sq. in. V in ft. per sec. $= \sqrt{2g \times H} = \sqrt{2g \times 208} = 115.2$ ft. per sec.

The quantity, therefore, in gallons per minute is $115.2 \times 50.27/144 \times 60 \times 7.5 \times 0.98 = 17{,}650$ g.p.m.

The total head is then $H = 208 + 4.5$ ft. $= 212.5$ ft.

The water horsepower is $\dfrac{17650 \times 212.5}{3960} = 947$ hp.

Efficiency is then $947 \div 2141 = 44.2$ per cent.

Taking next test No. 25, with the pump discharging through a 16-in. nozzle with 55 lb. discharge pressure, or 127 ft. head, and $18^1/_2$ in. of vacuum on the suction, and assuming the nozzle to be 98 per cent efficient, gives $A = 201$ sq. in. V in ft. per sec. $= \sqrt{2g \times 127} = 90.7$ ft. per sec.

The capacity in gallons per minute equals $90.7 \times 201/144 \times 60 \times 7.5 \times 0.98 = 55{,}800$ g.p.m.

The total head equals 127 ft. + 20.9 ft. = 147.9 ft.

The water horsepower is then equal to $\dfrac{55{,}800 \times 147.9}{3960} = 2082$ hp.

Efficiency is then $2082 \div 2700 = 77.1$ per cent.

These figures do not impress the writer as being especially good for a pump of this size. A test on a 6-in. pump of recent design showed an efficiency of approximately 56 per cent and 70 per cent under conditions corresponding to the conditions as given.

The writer cannot agree with the deduction to be derived from curves 11 and 12, Fig. 8, and would be interested to know on what data these curves were based.

The thrust may be said to be a function of the vacuum and of the discharge pressure. These depend on the capacity and on the peripheral speed of the impeller, regardless of the diameter; therefore, the thrust is not dependent on the diameter in any way except for the greater possibility of the pressure not being equal on the two sides of the impeller.

Curve No. 12 would indicate that the larger the clearance the lower is the thrust load. Increasing the clearances between the impeller and the casing increases the pressure on the shrouds; and if carried far enough it would result in the full pressure developed by the pump being exerted on each shroud. This of course would give a far greater difference in pressures between the front shroud and the back shroud than the figure arrived at; that is, for forced vertex. There undoubtedly would also be greater leakage, which would increase the positive thrust still further.

No doubt a study of the data from which curves Nos. 11 and 12 were made up, together with a detailed study of the pump construction, condition of the pump, amount of wear, etc., would explain these discrepancies.

In conclusion, the writer would state his views on the matter as follows:

1 Vanes should be provided on the outside of the impeller shrouds and carried as far down as possible, and the clearances should be kept as small as possible in order to approximate the conditions of a forced vertex.

2 The clearance between the front shroud and the casing should be somewhat larger than between the back shroud and the casing to increase the negative thrust on the front shroud.

3 The pump should be fitted with an adjustable sealing ring at the suction intake to reduce the leakage at that point to a minimum, not only because of the effect on efficiency, but also on account of its effect on the thrust as well. This can readily be seen by a study of the diagram, Fig. 10.

4 No relief holes should be used in the back shroud for practical reasons, as enumerated in the preceding.

NELSON OGDEN.[7] The authors describe in detail the method they used for calculating the thrust loads from the observed pressures. Briefly, they plotted pressures against radii and summed up the loads calculated for a number of small annular areas. Their method is partly graphical and partly arithmetical. It may be interesting to examine a purely graphical method that is quicker and more accurate and permits closer analysis of the influences at work.

The method consists simply in plotting the observed pressures against the squares of their respective radii, thus permitting a direct determination of the mean net pressure by using a planimeter. This pressure, multiplied by the total area of the impeller, gives the thrust load.

The real problem, however, is to work out a rule for calculating the thrust in any dredge pump. It should be made possible for different persons to agree fairly well on the maximum load to be provided for. Certainly the range mentioned by the authors, 48,000 to 160,000 lb., sounds too much like guesswork.

Examination of a typical pressure diagram, of the sort now proposed (see Fig. 11) shows that the thrust determination can be no more accurate than the diagram, since the thrust is proportional to the mean width of the loop. It is not easy to see

[7] Frankford, Philadelphia, Pa. Assoc-Mem. A.S.M.E.

what really affects this "fatness," which is roughly a measure of the degree of unbalance. It appears that one could start out with given impeller dimensions and suction and discharge pressures and draw a variety of equally plausible diagrams, with mean widths varying at least in the ratio of 2 to 1. Thus, we seem still to be far from an exact rule for figuring thrusts.

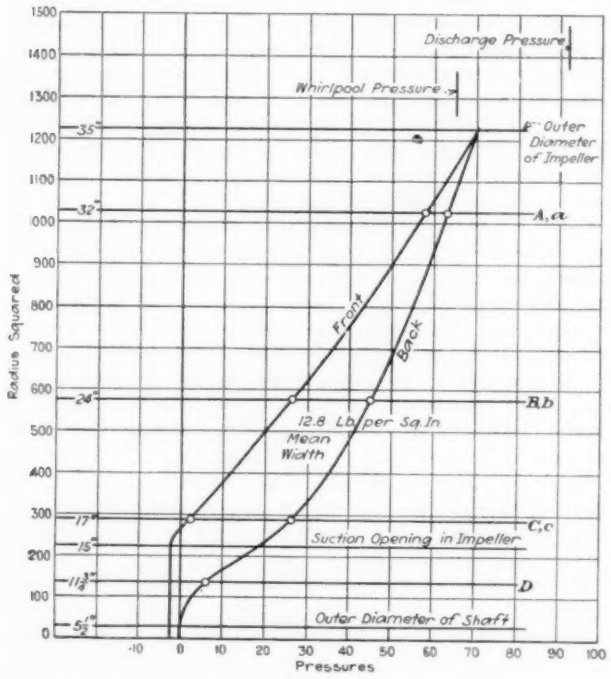

FIG. 11 GRAPHICAL METHOD OF CALCULATING THRUST LOADS

(Test run with 8-in. nozzle at 350 r.p.m.; 3848 sq. in. at 12.8 lb. per sq. in. = 49,200 lb. thrust.)

These remarks are certainly not intended as destructive criticism, but as an effort to show the need of further interpretation of the test results, and possibly new experimental investigation. It does seem that the authors have at least established general principles, such as the important effect of side clearances. The way has been paved for constructing characteristic curves as a guide in any specific problem.

ARTHUR B. LAKEY.[8] The authors have secured a wealth of authentic data concerning dredge-pump thrust loads, their causes and effects, and certain incidental or collateral conditions set up when it is sought to reduce the thrust loads.

One such collateral effect is reduction in the efficiency of the new pump when it is desired to lessen the net thrust load by using large side clearances. Another instance is accelerated wear favored by large initial clearances or by use of equalizing holes. The latter, even without notably affecting the new efficiency, seem to permit extensive short-circuiting, and hence rapid erosion of the runner. Pump efficiencies, through apparently omitted in working up the numerous tests reported, are so important that the authors have included them explicitly or by inference in three of their nine conclusions.

Attempts to supplement these test results by calculating the pump efficiencies show a need for more data on the resistances of the pipe lines and nozzles used. With additional information of this sort available, more reliable efficiency figures could be obtained, permitting study of the year-round mud-digging ability of a pump as affected by various thrust-producing conditions.

If extensive material-pumping tests appear desirable, the gage connections can be arranged for flushing with clear water under pressure prior to taking each reading.

The change in thrust load due to increasing the suction diameter of the impeller should be more generally appreciated. If this diameter is to be greater than the pipe-line size, the engineer should provide the extra thrust capacity that the excess involves.

If there is any one who can give an idea as to the relative

[8] Sales Engineer, Kingsbury Machine Works, Frankford, Philadelphia, Pa. Assoc-Mem. A.S.M.E.

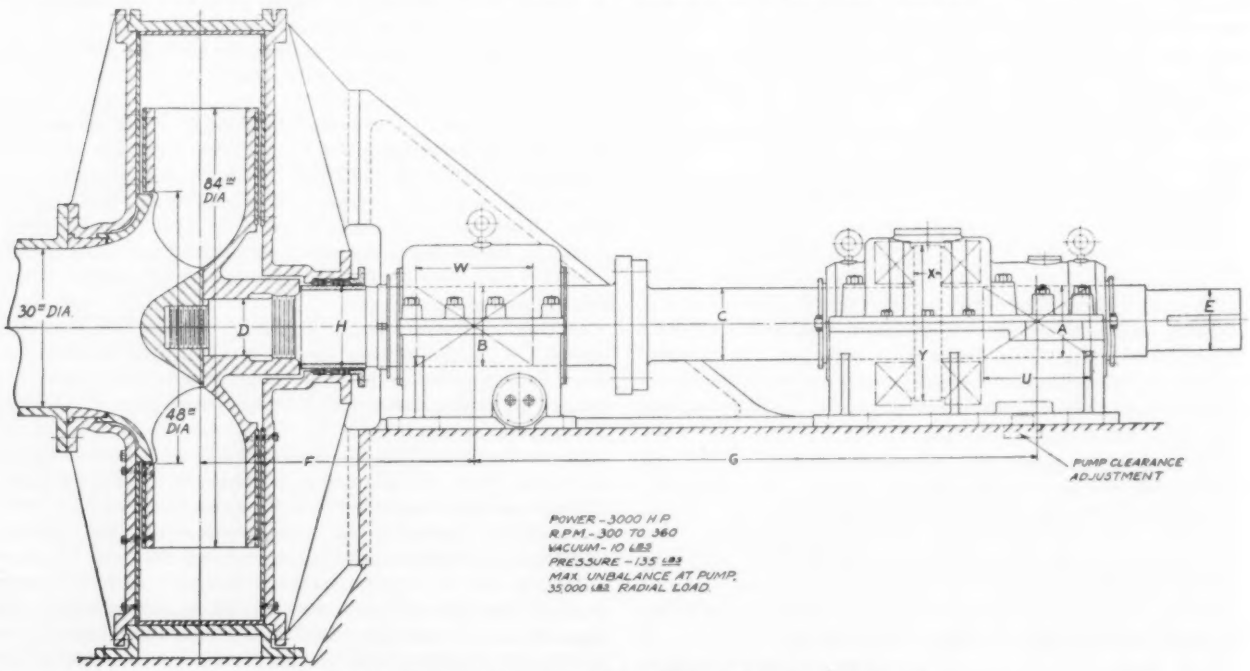

FIG. 12 TYPICAL ARRANGEMENT OF DREDGE PUMP AND BEARINGS

prevalence of rotors with external vanes as compared to those not so fitted, it is felt that the information will be most welcome. The authors' opinions are desired regarding the advisability of close radial fits at the outer diameter of the impeller. Such a construction, while a complication, would appear to help in combating short-circuit flow with its bad effects, and also to permit a closer approach to the whirlpool-chamber idea so largely used in moderate-power low-head pumps, with its reduced hydraulic losses.

Fig. 12 shows a pump arrangement followed largely on a number of recent dredges. The thrust bearing has about three times as much capacity on the working side as on the slack side. Inspection of such a dredge bearing recently, after extensive running, showed that the bearing surfaces had not been in metallic contact at any time during operation. Hence the 1 to 3 ratio advanced by the authors appears conservative.

The two journal bearings are designed to secure complete oil-film lubrication against large loads in any radial direction. They apply principles laid down in "A Graphical Analysis of Journal Bearing Lubrication," A.S.M.E. Proceedings 1923–4–5. The pedestal bearing near the impeller is self-aligning; that incorporated with the thrust bearing is rigid.

The maximum loads are taken as the algebraic sum of (*a*) the static loads and (*b*) a revolving load occasioned by a boulder filling an impeller passage and whirled at maximum revolutions per minute and at maximum radius. The greater unit journal pressures have been taken at about 100 lb. per sq. in.

The shaft diameter at certain points exceeds strength requirements to secure greater stiffness. The journals are purposely short to avoid needless friction and effects of shaft deflection.

All these bearings have suitable arrangement for automatic oiling and are thus independent of any oil-pumping system. With unusually high-powered dredge pumps it has worked out best to include an external cooler in the automatic oil system.

The "factor of ignorance" has been such that many dredges are over-supplied with thrust-bearing capacity. Taking the apparent extremes which have occurred within the writer's experience, we find on the basis of carefully estimated loads that the most daring case has relatively only one-fourth the thrust capacity of the most conservative.

The paper affords the best practical basis for attaining consistent yet safe thrust estimates that has reached the writer's attention. Engineers and operators who are faced with this problem should find the authors' results highly useful. These have been presented in a manner well adapted to stimulate discussion.

It is hoped that the authors may find it convenient to make further tests and to amplify the information already given. These tests may lead other experimenters to extend and supplement the investigations so well begun.

PIERCE J. MCAULIFFE.[9] The dredging fraternity is greatly indebted to Messrs. Polhemus and Healy for this paper, and all those who are interested in dredging problems will appreciate the work that has been done by the authors.

On the second page of the paper, under the heading, "Direction of Thrust Load," reference is made to occasional report of reversal of thrust load. It might be interesting, therefore, to add that I have seen a 10-in. dredge, working in a sand and gravel plant, where the thrust load was so nearly neutral that the impeller shaft was practically floating with only very slight movement toward the suction or away from the suction. The dredge pump was operating at 580 r.p.m. with discharge pressures ranging between 40 lb. and 45 lb. No measurements of thrust loads were made, but it was apparent from the action of the thrust bearing that the thrust load was very light. In the design of this pump there had been a conscious effort made to lighten the trust load.

The engineers of the Morris Machine Works, with which I am connected, have given much thought to the questions discussed in this paper. They agree with the views expressed by the authors in many respects, but they are at variance in other respects. Their conclusions are: It is possible to control or even to reverse the thrust on a dredging pump by (1) making the front shroud of larger diameter than the back shroud, (2) maintaining small clearance on the back side of the impeller, (3) allowing large clearance on the front side of the impeller. They do not consider relief holes necessary or desirable.

For the past several years none of the new designs of dredging pumps developed by Morris Machine Works has had relief holes in the impellers. We consider that relief holes produce circulation loss within the pump. Where circulation losses occur, wear on the pump parts becomes more active. Relief holes, through wear, increase in size, permitting increased circulation losses. Back liners have to be replaced more frequently. With the more rapid wear on the back liners, when relief holes are used, it is more difficult to maintain the small clearance on the back side of the impeller, which is one of the principal factors in reducing the thrust load.

To reduce the circulation losses which would otherwise occur with large clearance on the front side, an adjustable sealing ring is provided on the front side. This adjustable sealing ring is placed so as to control the clearance between the impeller and the suction disk at the suction opening of this impeller. As wear takes place the sealing ring is pushed in toward the impeller to keep the clearance a minimum.

We are convinced that circulation losses within the pump lower the pump efficiency. With the pressure and vacuum readings taken during the test it would be possible to make a sufficiently accurate computation of what the circulation losses amounted to if the size and number of the relief holes in the impellers had been stated.

During the discussion which followed the readings of the paper a criticism was made because the thrust load had been computed instead of being actually measured. I would like to add that I am thankful for the information presented. I realize how difficult it is to induce dredge owners to turn a plant such as this, with probable earning power of around $2500 per day, over to engineers for experimental purposes. I would also be very much interested in getting further information about a practical device for measuring the thrust load on a unit of the size referred to in the paper. What would the cost of such a device be? How could it be applied?

During the discussion two questions were asked concerning the design of the dredging pump presented to which I took the liberty of expressing my own views in answer. These questions were:

1 Is it customary practice to make dredging pumps of rectangular section as shown by Fig. 1?

2 Is it customary practice to have such an abrupt turn from suction piping into impeller as is shown by Fig. 1?

My answer to the first question is that by far the greater number of dredging pumps built have a whirlpool section beyond the perimeter of the impeller of circular shape or approaching the circular. From previous articles presented by Mr. Polhemus it is evident that he prefers the rectangular shape because it lends itself more readily to being fitted with casing liners. I believe that it is safe to say that more dredging engineers consider that it is cheaper in the end to do without casing liners and instead to make the casing very thick and to replace the entire casing when it is worn out rather than to have the more

[9] Hydraulic Engineer, New York, N. Y. Mem. A.S.M.E.

frequent shutdowns for renewal of casing liners. The casing on many dredging pumps is frequently made 5 in. thick to reduce the number of shutdowns necessary for replacement.

My answer to the second question is that recent designs of dredging pumps, as a rule, present a much easier entrance at the suction than is shown by Fig. 1. The cross-section of a 24-in. pump, shown by Mr. Ogden while reading the paper, had a much easier entrance at the suction, and such entrance is now followed more regularly than that in Fig. 1. There was another feature of the design presented by Mr. Ogden, which I think it well to comment on. The impeller vanes projected considerably into the suction opening of the pump. Lacking the other views of this same design, it would be my impression that the vanes of the impeller would converge to such an extent at the center as to restrict seriously the openings into the impeller. In the December 17, 1925, issue of *Engineering News-Record*, page 983, are shown two photographs of the accumulation of trash which was removed from the pump runner of one of Mr. Polhemus' dredges during a 24-hour run. These photographs will give an idea of why large passageways through dredging pumps are essential. A striking example of the improvement of output obtained by a dredging pump after it had been changed from one with rather restricted openings through

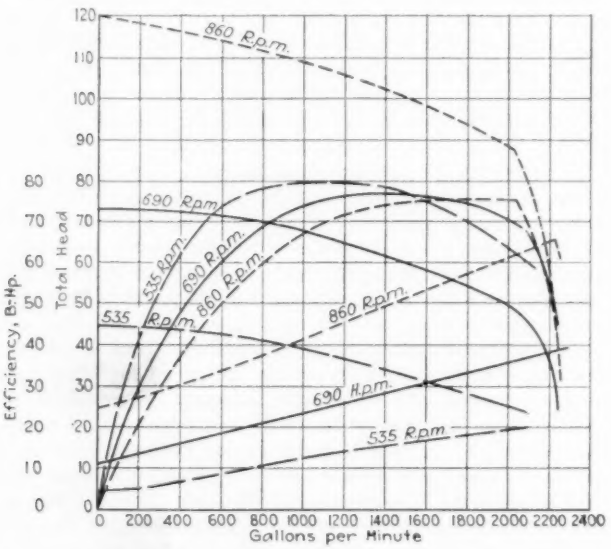

FIG. 13 TEST CHART OF 6-IN. DREDGING PUMP DESIGNED TO PASS OBJECTS UP TO $4^1/_8$ IN. IN DIAMETER

impeller to one with large openings will be found in the paper presented at the December, 1919, meeting of this Society by Mr. Walter J. White, of New Orleans.

In the discussion one inference I gained was that, while ruggedness had been provided for by dredge-pump designers, efficiency had been largely disregarded. This might have been true some years ago, but I am confident that it is not true today. I know that dredging pumps, particularly the smaller sizes, had rarely been credited with efficiencies higher than 50 per cent. To show that there has been an improvement in this respect I submit the test chart of a 6-in. dredging pump designed to pass objects up to $4^1/_8$ in. diameter (Fig. 13). This pump is one of a series, all of similar design, developed recently by Mr. V. J. Milkowski, chief engineer of the Dredging Department of the Morris Machine Works. The test was made on what has been adopted as the standard 6-in. medium-duty dredging pump. Other sizes of this same series are showing similar characteristics. As a matter of fact, some of the old designs, when tested at capacities above those usually credited to them, have shown surprisingly good efficiencies. According to my observations the low efficiencies obtained from dredging pumps have not been so much a question of design as one of application. Dredging pumps have been used too frequently at capacities too small to obtain good efficiencies.

LEWIS F. MOODY.[10] I fully agree with the points that discussors have accentuated covering the difference between the total thrust and that portion of the thrust which is calculated in the paper by measuring pressures in the clearance spaces. The title of the paper might mislead some readers to think that it gives rules for computing the total thrust on a pump.

As Professor Daugherty has pointed out, one factor is left out in the theoretical relation, that is, the impulse of the entering jet of water passing through the suction pipe. That water has to be turned at right angles and discharged radially. Therefore, right away we should include in the formula this expression WV/g, where W is the weight of water entering per second, V the velocity in feet per second, and g the acceleration of gravity. Even after we get that in we have not the whole story.

We know very well from many tests on hydraulic turbines and pumps of various types that when you measure the actual thrust you very often get quite a different result than when you attempt to compute by a certain method of analysis, such as this. Therefore, the final results that are given in this paper should not be mistaken for the total thrust of the pump, but only as an analysis of certain elements of that thrust.

Another point I might mention is that in looking at that first figure in the paper the design of this particular pump looks unnecessarily crude. We all realize that dredge-pump problems involve certain practical considerations which do not enter in ordinary centrifugal-pump designs—the handling of water containing large amounts of suspended material, the conditions of wear which have to be taken care of, and the necessity for a very simple design structure. Nevertheless, it rather offends the feelings of some of us who have been working in hydraulic design for a good while to see the attempt to make the water turn absolutely at a sharp right-angle at the transition from the suction pipe into the impeller. You will notice on the first design that there is an absolutely sharp angle at that point.

In the type of pump which Mr. Lakey showed in his discussion (Fig. 12) there has been a great improvement in the design at that particular point. A factor like that has an effect on the efficiency. Perhaps minor attention has been given to efficiency in many dredge-pump installations. As Mr. McAuliffe says, that problem is now being properly studied. But whenever you have an inefficient hydraulic design you always are in danger of other accompanying phenomena which are not any too good, such as localized erosion and pitting. I am inclined to agree with Mr. Knox that this dredge-pump problem should be attacked on properly theoretical hydraulic lines.

Another interesting thing that occurred to me is that I did not notice in the paper any comparison of the theoretical curve of pressure variations in these clearance spaces with the actual pressures attained. These two spaces are simply spaces bounded by two planes normal to the axis, and the variation of pressure should be in fairly close agreement with a parabolic relation. There was no attempt to compare the actual pressures with the theoretical curve of pressure in either of those spaces. I think it would be interesting to have that done.

I do not think that we should too strongly criticize an author for giving us what data he has been able to collect on tests just because we would like to have seen him obtain some more.

[10] Consulting Engineer, Cramp Morris Industrials, Philadelphia, Pa. Mem. A.S.M.E.

I think the authors should be complimented on submitting to us such results as they have been able to secure. At the same time, they do leave us an excellent field for further tests to find out what the actual results are on dredge pumps and on other types of centrifugal pumps.

Authors' Closure

While all suction dredge pumps are fundamentally of the centrifugal type, the term "dredge pump" was used in the title of the paper because the results as noted and discussed were obtained from actual tests on a dredge pump and we were concerned with the suction dredge pump only.

It remains for some one concerned with pumps designed for other than dredging service to determine whether or not the facts and principles as set forth in the paper are applicable to other fields. Likewise it remains for some one concerned with dredge pumps, who has the opportunity and available funds, to design, install, and operate a proper mechanism for measuring actual thrust in connection with dredge pumps of similar size.

It is agreed that more than one method of computing the data may be used, but as the method of obtaining the data was extremely simple and understandable to the average dredge operator, it was felt that the method of computation should also be simple for the same reason.

We appreciate Mr. R. L. Daugherty calling attention to our having left out the factor of the dynamic force of the water entering the impeller. However, as the thrust unit must be designed to accommodate a condition of maximum thrust and this condition occurs when discharge pressure is high and velocity of flow is low, it was felt this force would not be of sufficient magnitude to include in the computation and at least would be on the safe side. However, as the force due to suction vacuum is used and which is also low under a condition of maximum thrust, unquestionably the dynamic force of the flowing water should be included to complete the study.

Applying the correction factor of the dynamic force to Fig. 2, or the detailed method of computing total thrust load, we note that the suction vacuum is equal to 5 in.; this corresponds to a suction-pipe velocity of approximately 10 ft. per sec. in the dredge *Clackamas;* therefore

$$\frac{64.4 \times 4.9 \times 10^2}{32.2} = 980 \text{ lb.}$$

As this force is negative it must be subtracted from the original total positive, leaving a net correct total positive of 51,603 lb. instead of 52,583 lb.

Curves Nos. 11 and 12 were plotted from thrust loads computed from pressure data as obtained with the 70-in. diameter impeller operating with $^1/_{32}$ in. clearance front and back as Curve No. 11, and $^1/_4$ in. front and back as Curve No. 12, and applied to impellers assumed to be 60, 70, 80, 90, and 100 in. in diameter. That is, it was assumed that the pressures as read on the *y-Y* gages would be the same for all sizes if the gages were placed the same distance from the periphery of the impeller and when the pump is discharging against the same discharge pressure, as was the case with the 70-in. test impeller. Likewise, it was assumed that pressures on *A-B* gages would be the same if these gages were placed the same distance inside the periphery of the impeller; the *c-C* and *D* gages, if placed the same distance from shaft center and the *b-B* gages if placed midway between *a-A* and *c-C* gages.

These pressures were plotted against the proper radii for each of the various diameters and from the pressure curve drawn through, and the thrust load was computed in the manner described in the original paper.

As certain assumptions are used in this connection, the results are of course only approximate, but check with our findings by experience that impellers of large diameter do produce more thrust than those of like design and small diameter.

After a study of the discussions, it seems to be conceded by all that the most efficient dredge pump is one in which circulating losses are reduced to a minimum, also that thrust can be controlled by varying clearances as between impeller shrouds and heads. It seems in agreement and our tests have proved that close clearance at the back and more open clearance at the front produces less thrust, whereas the reverse condition produces high thrust.

In order to reduce circulation losses which occur between the the nose or seal ring and the suction disk of the impeller, it is necessary to maintain as small a pressure differential at this point as is possible. This can only be accomplished by the use of vanes running close to the front head and which eliminates the possibility of reducing thrust by an open front clearance and at the same time reduces circulation losses to a minimum at this point.

It is also in agreement that in order to reduce thrust it is necessary to maintain close clearance between the back head and back shroud vanes and that circulation losses at this point may be eliminated by the use of an impeller without relief holes. Therefore, it is reasonable to assume that a pump impeller without relief holes and with vanes on both front and back shroud running in close proximity to the casing heads will show the best efficiency although at the expense of a higher thrust load than would be the case if relief holes were used.

It was not intended in the paper to justify the use of relief holes except as they may affect thrust loads and which in the case of our test showed to be 118 per cent higher with relief holes plugged.

Mr. McAuliffe brings out in his discussion the reason why it was not practical to actually measure the thrust load. Not only would the testing apparatus be expensive, but the loss of dredging time would run into quite a considerable sum. It was for this reason that these tests were made to develop a means of computing the thrust loads on any type of dredge pump.

It is believed the data presented in this paper will give all interested parties sufficient information for them to determine the maximum size of thrust bearing for any given large high-powered dredge pump.

It is not often that one has the opportunity to make such a series of tests on a large dredge pump due to the expense involved in taking the dredge out of active service and the hesitancy of boring test holes in a new large pump casing. For these reasons it was felt this actual test data would be of interest to dredge-pump operators and builders.

The dredge-pump problem is quite different from that of a water pump or, in fact, any other type of pump, as the most important features are high output, low maintenance, and steady operation rather than high efficiency. The efficiency of this pump, however, was very good, the nozzle tests showing an efficiency of 61 per cent for a 2000-ft. pipe line and 55 per cent for a 10,000-ft. pipe line. Its performance under actual dredging operations has been most satisfactory even on pipe lines over two miles in length.

From a practical operating standpoint we feel that pump impellers with relief holes in the back shrouds are to be preferred to the closed back impellers. We find that the wear of either the relief holes or the back liner is not excessive and that relief holes do not reduce the output of the dredge.

The vanes on the outside of the impeller shrouds help the dredge operation in a practical way as they keep material from lodging between the impeller and the casing. They tend to reduce liner wear, and these impeller vanes themselves are

simple to renew. In fact, they and the various wearing rings must be renewed quite often if the pump clearances are to be kept close and uniform, which is most important if a large continuous output for the dredge is desired.

Adjustable nose rings are desirable in many instances especially where the unlined volute pump casing is used, though the practice of the Port of Portland has been to use renewable nose rings rather than adjustable ones, it being more practical to renew these rings from time to time as the pump is relined or repaired rather than to adjust the nose ring to insure a close fit while the pump is in operation. An effort is made to maintain reasonably close pump clearances at all times, and the dredge pumps are opened, inspected, and repaired or relined if necessary once a week, usually on Sundays.

The square casing with a full-lined volute as well as the abrupt suction entrance has been adopted to minimize the pump maintenance. The Port of Portland has found this type of dredge pump to be quite as efficient so far as practical dredging results are concerned as the rounded unlined volute or the pump with an eased suction entrance. The object which the Port of Portland has striven to obtain is to get the most number of cubic yards of sand into the fill for the least cost, and this type of pump has so far given the best results, though the Port has experimented with various shaped whirlpools and suction entrances. Where the material is clay, not abrasive, and has considerable trash in it, a less abrupt entrance is better. The object of this paper was not to discuss dredge-pump efficiencies and designs, but to give data relative to thrust loads and pressures inside the pump casing at various points, this being data which the usual pump tests do not show.

The latest dredge-pump design of the Port of Portland has an unlined volute and an adjustable nose ring on the suction side of the pump as well as an eased suction entrance.

The main object of the eased or flaring pump suction is to make it easier for the pump to pass sticks, rocks, and trash. The adjustable nose ring is used where the lighter renewable nose rings have to be replaced oftener than once a week due to the handling of very abrasive material. However, it might be of interest to know that the 30-in. pump with its abrupt suction entrance, as shown in the sketch, was a development based on the former use of the flared suction. This type of pump seemed to produce more yardage and was preferred to the flared suction type by the dredge operators when handling clean sand. When dredging clay or trashy materials, the flared type of suction is best, and the Port of Portland keeps both types of heads and runners on hand, and, in fact, on some of the pumps uses a combination front head permitting the use of either type.

For intermittent dredge operation or for the handling of light materials, the unlined volute is also preferable to the full-lined volute pump.

Thermodynamic Theory of the Air Lift

By ALEXEY J. STEPANOFF,[1] SAN FRANCISCO, CALIF.

The air lift as a method of pumping from deep wells is subject to no generally accepted theory that will serve as a basis for practical design. Treating the air-lift pump as hydraulic apparatus, the thermodynamic side of the phenomenon has been neglected, and this method will explain many points in the operation that now are obscure. In his conclusions the author decides that the efficiency of the air does not depend upon the form of the footpiece if the air-inlet devices do not obstruct the flow of water, if the openings for the air are sufficiently large to cause no impact, and if the air and water are so introduced as to secure uniform mixture. Attempts to introduce jet action of the air are due to misunderstanding the method of action. Slip losses are usually due to incomplete expansion of the air, the slip as such being not of much importance. No "single coefficient" experimental formula can express the variables involved in the air lift, as its operation depends upon factors which vary differently for various submergences, air-to-water ratios, sizes of pipes, etc.

1 Introduction

ALTHOUGH the air lift occupies a more and more prominent place among the methods of pumping liquids from deep wells, there is no generally accepted theory among the many proposed which will satisfactorily check with the experimental data and give a basis for practical design of the air-lift pump. All attempts to reconcile the discrepancies of the theories proposed with experimental data have failed, and until now many factors governing the operation of the air-lift pump are covered with the haze of mystery. The attempts to find some corrective factors for the existing formulas have sometimes gone so far as to lead to the introduction of terms that have no physical meaning. In the opinion of the author, the cause of such a situation lies in the fact that, considering the air-lift pump as hydraulic apparatus, the thermodynamic side of the phenomenon was neglected, while air under high pressure is best understood when treated thermodynamically.

Consideration of the air lift from a thermodynamical point of view has the advantage of not violating the scientific principles involved in the other theories. It throws light upon the operation of the air-lift pump which seemed obscure before and permits conclusions important from a practical point of view.

2 Operation of the Air-Lift Pump

As is well known, the air-lift pump consists of a bored well sufficiently deep to permit the liquid level to rise a certain distance above the bottom of the well. A pipe called the rising main or eduction pipe or lift tube is submerged in the liquid, and compressed air is introduced somewhere near the lower end.

Air bubbles rising through the water in the lift tube so reduce the specific gravity of the mixture, and therefore the weight of the column of the liquid, that the excess pressure at the base of the column due to external liquid pressure forces the mixture above the supply level and out of the top of the delivery pipe. This method of presentation of the operation of the air-lift pump was chosen here because it is easiest to understand; others will be given later. Different relative positions of the air pipe and water pipe are possible, but from the theoretical point of view they all are equal, though in practice certain combinations are more efficient than others.

3 Theories of the Air Lift

Among the most widely used theories of the air lift, those proposed by Prof. E. G. Harris, Dr. H. Lorenz, Prof. A. H. Gibson, and N. Swindin may be listed.

Professor Harris[2] considers the force of buoyancy of the air bubble as the motive force of the pump, analyzes the motion of the bubble, finds the relation between the size of the bubble, slip (relative velocity of the air bubble in respect to the water), and the head produced.

Dr. Lorenz[3] in developing his theory writes Bernoulli's equation for a differential head dh corresponding to a given flow in the discharge pipe, introducing variable pressure, density of mixture, and integrating between the limits $h = O$ and $h = h_s + h_d$ (Fig. 1), and thus he gets the relation between the variables involved.

Professor Gibson's theory, being simpler than these just given, will be quoted in detail as it is in his book:[4]

Let V_w = volume of water raised, in cubic feet per second
V_m = mean volume of air used, in cubic feet per second, during its passage through the rising main
V_a = volume of air used, in cubic feet per second, at atmospheric pressure P_a
P_1 = pressure at the base of rising main
h_d = net lift, in feet
h_s = submergence, in feet

Then assuming isothermal expansion of the air in the lift tube, we have:

$$V_m = \frac{P_1}{P_1 - P_a}\left(\log_e \frac{P_1}{P_a}\right)V_a$$

The mean specific gravity of the mixture in the tube is

$$\frac{V_w}{V_w + V_m}$$

Head producing flow $= h_s - (h_d + h_s)\dfrac{V_w}{V_w + V_m}$ feet of water, or

$$= h_s \frac{V_w + V_m}{V_w} - (h_d + h_s) \text{ feet of mixture in the lift tube}$$

$$= \frac{V_m}{V_w} h_s - h_d \text{ feet of mixture.}$$

Equating this to the sum of the friction head h_f and the kinetic head h_v we have, on reduction:

$$V_m = V_w \frac{h_d + h_f + h_v}{h_s}$$

hence

$$V_a = V_w \frac{P_1 - P_a}{P_a \log P_1/P_a} \cdot \frac{h_d + h_f + h_v}{h_s}$$

$$= \frac{V_w(h_d + h_f + h_v)}{34 \log_e P_1/P_a}$$

---

This relation enables the volume of free air per cubic foot of water to be determined in terms of h_f and h_s.

N. Swindin[5] contributes no new theory of the air lift, but throughout the proposed design procedure the losses are itemized; among the "so-called losses" such items as "acceleration" loss and slip loss are introduced.

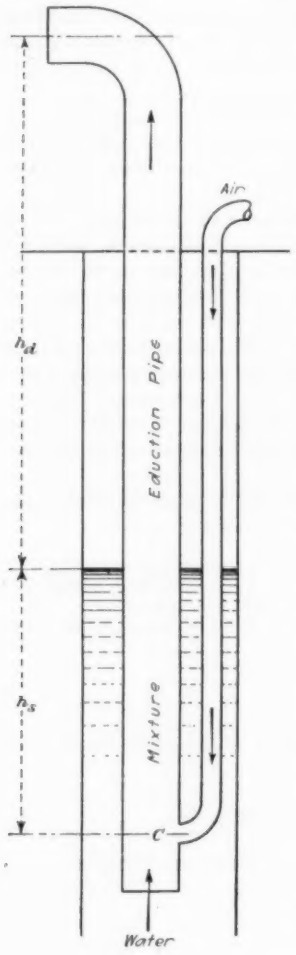

FIG. 1

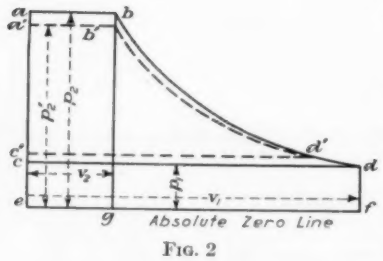

FIG. 2

THERMODYNAMIC THEORY OF THE AIR LIFT

Now the phenomenon will be approached from a different point of view. To make the matter clearer it is better to start from the air compressor and follow the air in all intermediate steps in its way from the compressor intake to the pump discharge. The work of compression of air consists of three parts: W_1, the work of charging cylinder; W_2, the work of raising the pressure of the air from some pressure P_1 and volume V_1 to some pressure P_2 and volume V_2 (Fig. 2); and W_3, the work of forcing the compressed air out of the cylinder.[6] W_1 is done on the side of the piston opposite to that on which W_2 and W_3 are performed in the same cycle; hence the total work of compression will be:

$$W = W_2 + W_3 - W_1 \ldots [1]$$

Assuming no clearance volume and isothermal compression, the work per pound of air

$$W_1 = P_1V_1 \text{ ft-lb} \ldots\ldots [2]$$

and

$$W_3 = P_2V_2 \ldots [3]$$

But

$P_1V_1 = P_2V_2$, hence

$$W_1 = W_3 \ldots [4]$$

And the total work of compression

$$W = W_2 = P_1V_1 \log_e P_2/P_1 = RT_1 \log r \ldots\ldots [5]$$

R being for air = 53.35; T_1 = temperature of air at intake, and r = ratio of compression.

On the PV diagram (Fig. 2) $W_1 = P_1V_1$ is presented by the area *cdfe*; $W_3 = P_2V_2$ is represented by the area *abge*, and $W = W_2 = P_1V_1 \log_e P_2/P_1$ by the area *bdfg* or *abdc*, as is evident from Equations [1] and [4].

If the compressor were equipped with an indicator, the indicator card obtained would be, in general, of the shape shown on Fig. 2 by *abdc*, and to a certain scale will represent the work of compression (from which the work of compression can be calculated) which if expressed in horsepower will be the indicated horsepower of the compressor, and which theoretically will be equal to $W = RT \log r$ per pound of air.

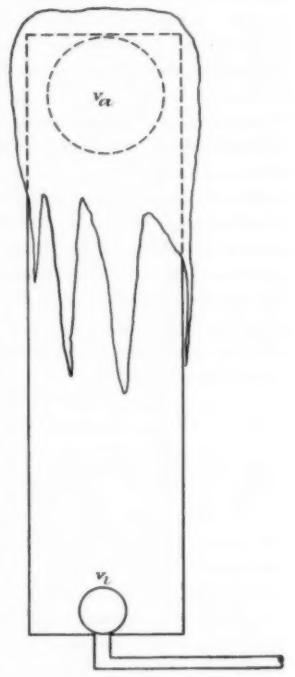

FIG. 3

The energy spent on compression is stored in the air and can be utilized in different ways. An air engine could be operated by the compressed air, and in an ideal case work done by this engine would be equal to that of compression. The indicator diagram of such an engine will be exactly the same as that of the compressor. Air would be admitted along the line *ab*, after which isothermal expansion would begin from *b* to *d* and exhaust from *d* to *c*.

But in the actual case, even assuming isothermal expansion, there are inevitable losses. For our purpose it is important to note that there is a loss of pressure from the air reservoir to the cylinder of the air engine. Instead of pressure P_2 there will be a pressure P'_2 lower than P_2, area *abd'b'a'* being energy lost due to the drop of pressure between the air compressor or receiver and the air engine. Also the pressure P_1 for an actual engine will be higher than that for the compressor by a certain amount, area *cdc'd'* being the loss due to incomplete expansion of the air in the air cylinder and back pressure during the exhaust.

The air-lift pump may be looked upon as an air engine and a displacement pump in one. If one pound of air is introduced at the pressure P_s, the volume being V_s, it is evident that during admission into the pipe the air will do the same work as if it were in the cylinder of the air engine; that is, P_sV_s. This work will be done by raising the water by displacement for the distance V_s/A, where A is the area of the pipe. The work done will be equal to the weight of water raised (Ah_sW) times the distance V_s/A through which the water is raised = $(Ah_sw)V_s/A = h_swV_s = P_sV_s$, where h_s is the submergence and w is the specific weight of the water. The same result may be obtained in the following way:

The height of the water column in the rising main above the water level outside the rising main will be V_s/A; thus the work done is equivalent to raising the volume of water V_s through the distance h_s, which will give again $V_swh_s = V_s(wh_s) = P_sV_s$ ft-lb., neglecting friction losses, of course.

It should be noted that when the air pressure is applied to the water during the starting period in the lift tube it will act upward and downward, but as the mass of water column in the eduction pipe is less than that outside of the pipe, the former will start moving, the outside column being brought in slight oscillation until the flow is established completely.

Air in the form of fine bubbles, or pistons occupying the whole cross-sectional area, begins to rise in the eduction pipe. While rising, the air expands isothermally, and finally escapes

[5] N. Swindin, "Modern Theory and Practice of Pumping," E. Benn, London, 1926.

[6] Carpenter, R. C., and Diederichs, H., "Experimental Engineering," p. 954.

with water or alone at the discharge. Expanding air does work exactly in the same manner as it would in the cylinder of the air engine, no matter whether it stays in one place or moves with water or slips through the water, because as soon as there is an increase in volume there is work done on the water. If the air during its rising completes its expansion or escapes at atmospheric pressure, the work done would be $W_2 = RT\log_e P_s/P_a$, P_a being atmospheric pressure and T temperature of water in the well. Thus the air gives out completely the work done upon it $W_3 + W_2$, as it would in an ideal air engine; from this work $W_1 = P_aV_a$ must be subtracted corresponding to the exhaust stroke of the air engine, which is the work done on the air, the net work done being:

$$W_3 + W_2 - W_1 = P_sV_s\log_e P_s/P_a = RT\log_e r.$$

Thus it would appear that moving the air does not change the availability of the work of expansion of the air, the only objectionable effect of the slip being the tendency of air bubbles to coalesce and rush out of the rising main at a pressure higher than atmospheric, without completing its expansion, the loss being due to incomplete expansion rather than to slip. Of course, a certain amount of work is consumed by internal friction of air and water during the slip, but later it will be shown that this loss is of small importance.

The work done by the air is utilized for raising V_w cubic feet of water per second through the distance h_d and in various losses such as friction losses, entrance loss, and velocity-head loss. These losses can be accounted for by introducing corresponding heads lost: h_f = head lost due to friction in the rising main; h_e = entrance loss head; h_v = velocity head. Head lost in the elbows may be included in friction losses by introducing the equivalent lengths of pipe in addition to the actual length of the rising main.

Thus, we may equate:

$$W(RT\log_e P_s/P_a) = V_w.w\,(h_d + h_f + h_e + h_v)$$

where W = weight of air used per second in pounds and w = specific weight of water = 62.3 lb. per cu. ft.

Air in the air-lift pump performs the discharge stroke of the ordinary displacement pump, the static head outside of the rising main completing the suction stroke by filling the space liberated by the air, the pump being "uniflow;" as reciprocating members are absent.

It is frequently thought that air bubbles rising through the water do no work, but just slip. This is not true in an actual case; air rising through the water column expands, and in expanding it does work. The work available from the rising air bubbles is a function of a particular installation.

Suppose a standpipe full of water and that volume V_1 of air under pressure P_1 sufficient to overcome the static pressure due to water column is introduced into the pipe near the bottom; immediately a volume of water V_1 will overflow from the standpipe, and water will continue to overflow until the air bubble rises to the top of the pipe, the total volume of water displaced being $V_1\ P_1/P_a$ where P_a is atmospheric pressure. If a series of bubbles is introduced into the pipe, water will overflow, but larger and larger volumes of air would be required to maintain the flow, which at least would stop, though the air bubbles would rise through the water. But this does not mean that air does no work. It does, but the conditions are similar to those of a centrifugal pump at impending delivery, or for any pump with the suction more than 34 ft. Energy is applied to the water, but it is spent on whirling water and finally in heat. Properly speaking, the static head outside the rising main does the same for the air lift as the static atmospheric pressure does for all pumps; it delivers water which is raised by the pump, or air, in the air lift. No pump can deliver water unless the water is delivered to it by atmospheric pressure.

5 Work Equation From Consideration of Force of Buoyancy and Difference of Densities of Water in the Rising Main and Outside of It

Now the problem may be looked upon from a different point of view. Suppose in the air-lift pump a volume V_s of air is introduced near the bottom, it must be at the pressure $= h_s.w$. This air possesses a certain amount of energy equal to the force of buoyancy $= V_sw$ multiplied by the distance h_s through which this force may act, in the same manner as a weight W lb. elevated a distance h ft. possesses the energy equal to Wh ft-lb. In addition the air has a certain amount of energy of compression, which increases the volume of air during its rise along the rising main; thus the force of buoyancy will increase also until at the top it will be V_aw, V_a being equal to V_sP_s/P_a. The mean volume of air during its rise will be

$$V_m = \frac{P_aV_a\log_e\dfrac{P_s}{P_a}}{P_s - P_a}$$

hence the mean force of buoyancy will be

$$\frac{(P_aV_a\log_e r)\,w}{P_s - P_a} = V_mw$$

and the total work done by the air will be equal to

$$\frac{P_aV_a}{P_s - P_a}(\log_e r).w.h_s$$

but $h_s.w = P_s - P_a$; hence the total work done by the air is $P_aV_a\log_e r$. This work is utilized in raising water and overcoming the various losses, or

$$P_aV_a\log_e r = V_w.w.h_d + \text{losses}$$

which is the same equation as the foregoing, deduced by thermodynamic reasoning.

Professor Gibson, considering the decrease in density of mixture in the rising main, deduced the equation (as already quoted from his book) as

$$V_a = \frac{V_w\,(h_d + h_f + h_v)}{34\log_e P_s/P_a}$$

$$= \frac{V_w\,(h_d + h_f + h_v)}{P_a/w\log_e P_s/P_a}$$

or

$$V_aP_a\log_e\frac{P_s}{P_a} = V_w.w(h_d + h_f + h_v)$$

which is, again, the same equation as the preceding two.

From this equation the relation between volumes of water and air may be obtained as soon as h_f, h_e, and h_v are determined.

6 Work Equation in Complete Form

The following equation of work was developed:

$$W\left(RT\log_e\frac{P_s}{P_a}\right) = V_w.w.(h_d + h_f + h_e + h_v)\ldots\ldots\ [1]$$

where h_d = the net lift, h_f = head lost due to friction in the rising main and fittings, and can be expressed as follows:

$$h_f = \frac{f(h_d + h_s + h')\, v^2}{2\, g.m} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

where m = the hydraulic mean depth, h' = additional length of pipe to compensate the friction loss in elbows, v^2 = the mean square of the velocity in the tube, which is equal to

$$\frac{1}{(P_s - P_a)A^2} \int_{P_a}^{P_s} \left\{ P_a^2\, V_a^2 \frac{1}{p^2} + V_w^2 + 2\, P_a V_a V_w \left(\frac{1}{p}\right) \right\} dp$$

which upon integration and reduction takes the form

$$\frac{1}{A^2}\left(V_w^2 + \frac{2V_wV_a}{r-1} \log r + \frac{V_a^2}{r} \right) \quad \ldots\ldots\ldots\ldots [3]$$

where A = area of the pipe and r = ratio of expansion of air = P_s/P_a. As an approximation, the value of V^2 may be taken as

$$V^2 = \left(\frac{V_a/2 + V_w}{A} \right)^2 = \frac{1}{A^2}\left(V_w^2 + V_aV_w + \frac{V_a^2}{4} \right) = \left(\frac{V_a + 2V_w}{2A} \right)^2$$

$h_s = k\frac{V_1^2}{2g}$, k being an energy coefficient for entrance loss and V_1 velocity of water below the air inlet

$= V_w/A$

$$h_v = \frac{1}{2g}\left(\frac{V_a + V_w}{A} \right)^2$$

Substituting these terms in Equation [1], we get the equations from which the values of V_a per unit of water can be obtained in terms of h_d, h_s, f, k, and A.

The value of coefficient f has been determined by Professor Gibson for a mixture of air and water, the friction head being expressed in feet of column of the mixture in the eduction pipe, from the published data of a large number of trials on such pumps. In every case f had a value approximately six times that obtained for the flow of water alone at the same velocity. It is evident that the value of f determined in this manner would take account not only of friction loss but also losses due to incomplete expansion of air and slip. The attempts to separate these losses were not successful. The chief reasons are the absence of data concerning friction of mixtures of liquids and air conducted under conditions excluding expansion and slip (horizontal pipes provided with means for intimate mixing of air and liquid). As soon as these data shall be determined for different ratios of liquid and air and different velocities of mixture, there will be no difficulty in separating this loss from those due to incomplete expansion and slip.

APPLICATION OF THE THERMODYNAMIC THEORY

It was shown that by thermodynamic reasoning we can deduce the same equation connecting the lift, submergence, and volumes of air and water as by other methods, but the thermodynamic reasoning enables us to go further and make a few conclusions important for practical application.

7 Form of the Footpiece

The "footpiece" in the air lift is understood to be the lower part of the pump; i.e., the end of the rising main and the arrangement for introducing air. Considering the air lift as an air engine and displacement pump, we have seen that if all losses above the footpiece are neglected, the work given out by the air is equal to the total potential energy of compressed air stored in it, and hence any ingenuous design of the footpiece cannot save any energy lost above the footpiece. The requirements for the design of the footpiece are the same as those for any engine, i.e., that the area of the opening must be sufficient to introduce the necessary quantity of air with the same velocity as that of the water, thus avoiding shocks or throttling, and then the air-introducing devices should not obstruct the flow of water or mixture. From the point of view of these requirements the best forms of the footpiece would be those shown in Fig. 4, *A* and *B*. For the purpose of reducing losses due to incomplete expansion and uniform flow at the intake it is important to introduce air in the form of fine bubbles, intimately mixed with water; hence the total area for the air inlet should be divided into a great number of small holes. As to the form of the lower part of the rising main, the same rules apply as those for any pump; to decrease the entrance loss the trumpet form has definite advantages.

There are many footpieces in use attempting to involve the jet action of the air in the air lift. Their appearance is due to confusing the method of operation of the air lift with that of an injector or jet pump. It seems that there never were any serious attempts to base the theory of the air lift on the jet principle; it should be remembered that at usual proportions of air to water the weight of air is negligibly small as compared with that of water. Thus the velocity of air must be very great to make appreciable effect upon the water. But an increase in velocity can be obtained only by restricting the area of the inlet and by an increase of pressure of the air back of this restriction, which means an increase of the load on the compressor. This increase in pressure must be considerable, as the volume of air at the pressure existing at the footpiece is comparatively small. As the conversion of the pressure energy into kinetic energy is always accompanied by the losses due to friction in the nozzle or orifice, it is evident that all these appliances only consume power, which was very well shown by extensive experiments by the Westinghouse Air Brake Company (1800 different experiments), Professors Davis and Weidner, and others.

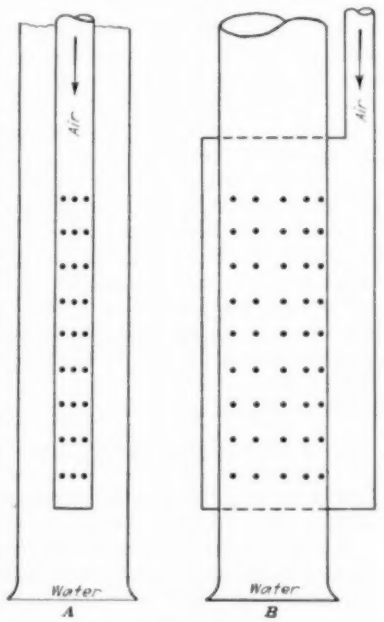

Fig. 4

From the point of view of thermodynamics it makes no difference if the air is introduced in small bubbles or large bubbles, but taking into account that large bubbles at the footpiece interfere with the flow of water and are liable to coalesce at the top and form streams discharging directly into the atmosphere without completing expansion, the smaller sizes of air bubbles uniformly distributed give better results.

The elongation of the rising pipe below the air inlet is important for two reasons: (1) If air is admitted in large quantities, the air bubbles may get outside of the pipe and be lost; and (2) when the pump is started, the air pressure acts upward and downward, and to start the pump it is essential to have a

certain excess of water column outside of the pipe, which insures steady and quick operation of the pump at the start.

8 Slip

It has been pointed out already that if the expansion of the air is completed or if air escapes at atmospheric pressure the slip has no effect upon the efficiency of the pump except for small losses due to internal friction of water and air. In other words, if the air escapes at atmospheric pressure it carries with it no energy put into it by the compressor. Very interesting and instructive experiments were conducted at the University of Wisconsin by Professors Davis and Weidner upon the behavior of the air bubbles in the air lift. They used $1^1/_4$-in. glass pipe for the rising main. The results of their observations are exactly the same as those of Professor Josse in Germany,[7] who used 3-in. glass pipe.

These tests showed that when air is admitted at a very slow rate the bubbles take the form of convex lenses with sharp edges, with the convex surface upward, the lower surface being quite flat; the bubbles occupied almost all the cross-section of the pipe. When the rate of discharge air was increased, the bubbles took the form of pistons separated by cylinders of water, and in both cases the flow was steady and uniform without any disturbances. Near the top, the bubbles rushed through the water pistons, and the water slipped down, forming larger water pistons. When these water pistons were long enough to prevent the air from rushing through them, they were discharged. The shape of the bubbles shows that they are moving under pressure from below; if there should be a slip, they would take the form of least resistance, i.e., elongated in the direction of motion.

From this we see that there is little tendency for the air bubbles to slip, except near the top of the discharge pipe, and that water slipped down does not slip through all the pipe, because the pipe along its full length is filled with alternate water and air pistons moving steadily and uniformly. The slight disturbances are only changes of distribution of water and air pistons, and only the discharge of air at a pressure higher than atmospheric produces a loss.

It should be noted that the foregoing refers to the air lift when the flow is established and the water overflows at the top. The behavior of air bubbles and pistons is quite different when there is no flow or when the supply of water at the bottom is not sufficient. Then, naturally, the air is forced out through the water layers, thus dissipating its energy on friction and discharging at a higher pressure. This condition is similar to that of any pump without a sufficient supply of water on the suction side. In this case the air lift has the advantage in comparison with the displacement pumps in that no damage occurs, the only result being loss of energy.

In case the air is mixed with water very intimately and remains in the form of bubbles at the discharge, its pressure is higher than atmospheric, due to surface tension.

It is important to separate these two losses—namely, loss due to slip and loss due to incomplete expansion—for the analysis, as they have different effects on the efficiency at different submergences. The first one is proportional to the length of the rising main or time required for air to pass the rising main. The second is dependent upon the ratio of water to air. Its absolute value is independent of the submergence, being controlled by the conditions at the discharge.

9 Effect of the Submergence Upon the Efficiency of the Air Lift

It was found by many experimenters that for constant input in foot-pounds the efficiency of the air lift increases with the increase of the submergence until a certain maximum is reached, after which the efficiency begins to drop.

Thus far no explanation of this fact has been given, this point being one of the mysteries of the air lift. And it seems really mysterious, for, with an increase of submergence, the lift being constant, the length of the pipe increases for both the air and water pipes; hence friction losses increase and loss due to slip should increase also, because the time for the air to pass the eduction pipe is greater. Then what makes the efficiency increase?

The answer is quite simple if we look upon the air lift as an air-engine-displacement pump and construct its indicator card, as explained, for two submergences. The increase in the submergence requires an increased air pressure. Thus if we construct indicator cards for one pound of air the height of the diagram for the greater submergence will be greater than for the smaller submergence, the lower parts of the cards being the same for both cases. It was shown that the area *cdlk* (Fig. 5) is loss due to incomplete expansion of the air, or discharge of air at a pressure higher than that of the atmosphere. This loss is constant for one pound of air, if the method of introducing the air is the same for all submergences, and it depends only upon the volume of air at the discharge. The work done per pound of air for the smaller submergence is represented by the area *efdc;* that for the greater submergence will be represented by the area *abcd*. The loss due to incomplete expansion is the same in both cases; thus it is evident that this loss expressed in per cent of the input will be less for the large submergence than for the small one.

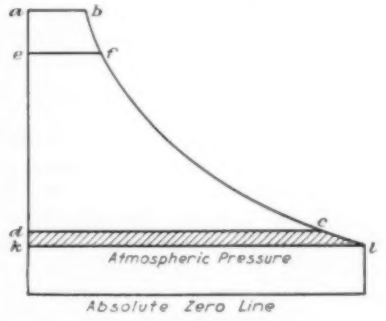

Fig. 5

If the increase in losses due to friction in the air pipe and the rising main could be estimated accurately it would be possible to predetermine the point of maximum efficiency from the study of indicator cards for different submergences.

10 Effect of the Increase of the Diameter of the Rising Main Upon the Efficiency

From the experiments of the Westinghouse Air Brake Company, Professors Davis and Weidner, and others, it was found that for the same submergence the efficiency of the air lift increased with the increase of the diameter of the eduction pipe. With the increase of the diameter of the rising main the velocity of the mixture decreases, thus decreasing the friction loss and velocity-head loss. Now, the decrease of velocity of mixture for a constant length of the eduction pipe means that the time for water and air to pass from the footpiece to the discharge will be greater, hence the slip loss should increase; the fact that efficiency increases with the increase in diameter of the eduction pipe clearly shows that the friction loss constitutes a more important part of all losses than the slip (the loss due to incomplete expansion being constant for both cases).

11 Effect of the Ratio of Air to Water Upon the Efficiency

All experimenters agree that the efficiency of the air lift is highest for the lowest rates of pumping, provided the continuous

[7] Josse, E., "Druckluft-Wasserheber," *V.D.I. Zeit.*, vol. 42, p. 981, Sept. 1898.

discharge is established; or, efficiency decreases as the input increases. If the slip is the main source of the losses, the opposite results would be obtained for the lower rates of pumping, because the low rate of pumping means low velocity, hence greater time for the air to slip. Then it would seem that the slip would be less for greater inputs of greater rates of pumping, because greater input at a constant submergence means a larger quantity of air; but with greater quantities of air, air bubbles tend to form pistons separated by layers of water which move uniformly without slipping until they reach the top of the pipe. Thus for greater inputs, the time for the bubbles to slip is less and the tendency to slip is less, hence it would be natural to expect that efficiency would increase. But experience shows the opposite, which is again the indication that losses ascribed to the slip are really due not to slip but to some other cause.

12 Effect of Introducing Compressed Air Above the Surface of Water in the Well

One of the mistakes resulting from a misunderstanding of the principle of operation of the air lift is that of introducing compressed air above the water level in the well. It has been shown that the role of the static pressure outside of the eduction pipe is exactly the same for the air lift as that of atmospheric pressure in the case of any other type of pump; that is, to supply water raised by the pump. The same line of reasoning as in the case of the air lift would lead to the conclusion that the application of the air pressure upon the surface of the water in the well or open pond would be advantageous for any kind of pump, especially for centrifugal pumps, which are so sensitive to a variation in the suction head. The advocates of this measure overlook the fact that the water level in the well is just an indication of the water level of the underground water which controls the flow of water into the well, and the attempts to increase static pressure in the well have no effect upon the static head of this underground reservoir. Hence it is natural that experiments conducted by Davis and Weidner could not reveal any effect of the additional static pressure in the well.

13 Effect of the Climate Upon the Efficiency of the Air Lift

There is no uniformity in calculating the efficiency of the input to the air-lift pump. The efficiency of the air lift as usually determined is the ratio of water horsepower, $Qwh_s/550$, to the input or air horsepower. The latter expression is differently interpreted by different writers; sometimes the air horsepower means the input in horsepower calculated from the theoretical air pressure at the footpiece, or $h_s.62.3/144$ lb. per sq. inch; sometimes as the same based upon the air pressure at the well, and sometimes the air horsepower is taken as actual indicated horsepower of the air compressor. For comparison of different air-lift pumps between themselves and with other types of pumps the last method of calculating the input should be used as it is more definite, while in the case where an air compressor supplies air to many air-consuming machines or is located too far from the well, the second method—i.e., the air horsepower based on the air pressure at the well—is preferable. The first method is impracticable for actual tests because the air pressure at the footpiece cannot be directly obtained. That calculated from the submergence may differ considerably from the actual, as it depends upon the design of the footpiece and the rate of discharge of the air. For theoretical consideration or design the input may be taken as based on the theoretical air pressure, but for calculating the probable efficiency of the pump the air pressure at the surface of the ground should be used, which would lead to the more accurate consideration of the air pressure losses in the air pipe, neglected in many instances. Besides the losses due to friction in the air pipe in calculating the efficiency, or comparing efficiencies of different air-lift pumps, or analysis of losses occurring in the air lift, the temperature of the surrounding air, the temperature of the air at compressor discharge, and the temperature of the water in the well should be taken into account. It should be remembered that in cooling air each five degrees on the Fahrenheit scale results in a loss of energy of about one per cent. No doubt the discrepancies in results of many tests are due to the neglect of this fact. In all data published on the air lift the data concerning the temperatures of water, air, etc., are absent.

While it is always assumed that the compression of air in the air compressor is isothermal, it is never isothermal in practice even with efficient cooling. Thus air leaves the compressor cylinder at a temperature higher than that of the surrounding air, which requires more power for compression. Air during the passage through the receiver and pipes begins to cool, and at the moment of its entrance into the footpiece it is cooled to the temperature of the water in the well, which might be considerably lower than that of the surrounding air at the surface of the ground. The average temperature of the ground water in the deep wells is about 50 deg. fahr., and varies little during the year. The temperature of the surrounding air might reach 90 or 100 deg. fahr., or even higher during the summer time and the temperature of the air at the compressor discharge will be still higher. Thus in this case the loss due to the cooling of the air will not be less than 10 per cent, assuming isothermal compression. For adiabatic compression, this loss will be still higher. It is therefore evident that, other conditions being equal, the efficiency of the air lift depends upon the climate and the efficiency of cooling the compressor.

In the most favorable conditions, assuming the surrounding air at 70 deg. fahr., water at 50 fahr., and isothermal compression, the loss due to cooling exceeds those due to entrance resistance and velocity head.

The foregoing discussion suggests the utilization of the air discharged from the well at the air-compressor inlet. This may be done in practice by installing a special air separator working at atmospheric pressure on the discharge pipe. Thus the same air is used over and over, and works on a closed cycle.

An interesting modification of this system from the theoretical point of view is the air-lift system with a booster; the compressor inlet is connected to the booster. This system consists of the air-lift pump discharging a mixture into a closed vessel on the surface of the ground. Here air is separated from the water and occupies the upper part of the vessel, while the water is forced through the outlet at the bottom by the air pressure maintained in this chamber. The compressor intake is connected to this chamber, using cooled air at a pressure higher than that of the atmosphere. This system forms a completely closed circuit similar to the condensing-steam-engine plant. The advantages of this system are (1) economy due to using cooled air, (2) the pressure of the air escaping without completing its expansion, or slip, is utilized by the compressor, and (3) the part of the eduction pipe above the surface of the ground carries only normal water at a lower velocity, therefore with smaller losses. Small additional losses are present due to velocity head and entrance loss at the booster.

There are no data available upon the actual operation of pumps of this kind, although several patents were given out in 1924. The complications in this system might arise from the fact that air might carry with it too much water into the compressor and, in turn, water will carry with it a portion of the air from the system, thus requiring a make-up of the quantity of air circulating.

14 Conclusions

1 Treating the air-lift problem thermodynamically has a definite advantage over the other methods, explaining many points of the operation of the air lift which are obscure when treated from other points of view.

2 The efficiency of the air lift does not depend upon the form of the footpiece if the following conditions are fulfilled: (*a*) That the air-inlet devices do not obstruct in any way the flow of water; (*b*) that the air-inlet openings are sufficient to give a velocity of air approximately equal to that of the water (no impact); (*c*) that the method of introducing the air insures uniform and intimate mixture of air and liquid.

3 All attempts to involve kinetic (jet) action of air in the air lift are due to misunderstanding of the physical side of the phenomenon, and are influenced by the method of action of an injector and a jet pump working on quite different principles.

4 Losses usually ascribed to the slip are chiefly due to incomplete expansion of air; the slip as such is of little importance.

5 Introducing compressed air above the surface of water in the well has no effect on the output of the pump, except possible loss of air through the leaks.

6 The motive force in the air lift is the potential energy of the compressed air, the static head outside of the rising main performing the same function as the atmospheric pressure in any other types of pump.

7 The efficiency of the air lift based on the indicated horsepower of the compressor or the air horsepower calculated from the pressure at the well depends upon (*a*) the method of compressing the air, (*b*) the temperature of the surrounding air, (*c*) the size of the air duct, and (*d*) the losses at the air inlet due to local obstruction in the form of nozzles, etc.

8 No "single coefficient" experimental formula can express the relation between the variables involved in the air lift, as the operation of the air lift depends upon several factors which vary differently for various submergences, air to water ratios, sizes of pipes, etc.

Some Interesting European Hydraulic Turbine Research

By BLAKE R. VAN LEER,[1] WASHINGTON, D. C.

IT IS the purpose of this paper to bring to attention certain turbine researches and their results which, although publicly known in Europe, are not generally known to the engineering profession in America.

The attitude of the hydraulic-turbine industry in Europe seems slightly different from that found in America. American engineers have a long list of brilliant accomplishments to their credit, but of recent years these have been brought about by dire necessity. It appears that most hydraulic engineers with American firms must convince their management that hydraulic experimentation and research are absolutely necessary before any money is forthcoming with which to conduct these researches.

In a great many European factories a definite research staff is maintained always at work on research problems, and if there are not any immediate problems, the solutions to which are required by the factory or by the practice, the staff is set to work on a problem which may yield information of benefit. Since labor, and especially technically trained and skilled labor, is much cheaper in Europe than in America, it is possible to maintain this highly technical work at a much less cost than in this country. Hence, from a standpoint of quantity of research and data collected on the subject of hydraulic turbines, Europe seems to have assembled the most. Furthermore, the majority of our American contributions have been the result of a few months' thought and experimentation, sometimes perhaps a few years, but abroad the tempo is vastly different. Europeans work with patience and thoroughness for years upon a problem.

Extensive Use of Models

As is well known to all hydraulic engineers and designers, our turbine theory is very imperfect. Consequently, after the theory has given a lead, the only sure way of ascertaining the truth is by investigation. Hence it is common practice here as in Europe to employ models for experimentation. This is done not only on account of its great cheapness, ease, and convenience, but also because our knowledge of the laws of similarity has increased so much in recent years that these tests are quite accurate within engineering limits. However, this use of models is much more common and extensive in Europe.

Dr. Thoma on Hydraulic Experimentation

The best article thus far published giving the European viewpoint on experimental research is "Experimental Research in the Field of Water Power," by Prof. Dr. Ing. D. Thoma, of the Technical University of Munich. Dr. Thoma very forcibly points out the value of experimental research when he says: "Theory, even if logically deduced, is unable to explain the complex facts of reality on account of the simplifying and not always exact assumptions underlying all theories. . . . These theories must be supplemented by experimental research. . . . The whole German turbine design has been based for a long time upon experimental research."

The weight of this statement is all the greater because Dr. Thoma is thoroughly grounded in all the turbine theories and is one of Germany's greatest teachers of theories. Although the paper quoted is over two years old, it is well to point out some research contributions that it mentions.

The first is the method of using parameters to designate vane surfaces. This makes it possible to classify, designate, and compare research data concerning very complex surfaces. Dr. Lawaczeck is given credit for this contribution.

The second is the value of having a standard method of designating similar things. Such a scheme makes it possible to compare results of research in different countries. Dr. Thoma suggests the use of absolute coefficients which would be the same regardless of the systems of measurements used.

The third contribution is that the conditions which exist for cavitation, as first shown by H. B. Taylor and L. F. Moody at the Hydroelectric Conference at Philadelphia in 1922, namely $\sigma = \frac{Ha - Hs}{H}$, can be used in model cavitation tests provided the proportion $\frac{H_1}{D_1} = \frac{D}{H}$ be maintained. This offers an extensive field for cavitation experiments with models.

The fourth is the visual study of hydraulic research problems, which is much more extensively practised in Europe than in America. By means of glass walls, stroboscopes, etc., one can frequently see when trouble is starting and what produces it when it is impossible to predict it by any known mathematical means.

Dr. Thoma has also listed the hydraulic-machinery laboratories of Germany. These are given in Table 1.

[1] Assistant Secretary, American Engineering Foundation; formerly Assistant Professor of Mechanical Engineering, University of California. John R. Freeman Scholar, A.S.M.E. 1927–1928. Mem. A.S.M.E.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, December 3 to 7, 1928, of The American Society of Mechanical Engineers.

In addition to these laboratories, there are others at Budapest; Vienna; Gratz; Prague; Stockholm; Gothenburg; Copenhagen; Padua; Milan University; Riva Construction Company, Milan; Winterthur; Zurich University, Escher Wyss, Zurich; Geneva, Ateliers des Charmilles; Grenoble University, Electro-Technique Grenoble; Toulouse; Paris; Teddington; Edinburgh; Manchester; etc. These constitute the chief laboratories of Europe which are continually making contributions to the advancement of hydraulic-turbine research.

There are numerous minor mechanical details in European practice that are of interest to American engineers. An excellent treatment of these will be found in "Observations on European Water Power Practice," by A. J. R. Houston, *Journal* of the Boston Society of Civil Engineers, October, 1926, vol. xiii, no. 8.

Efficiency Formulas

In the use of model turbines European laboratories apply the

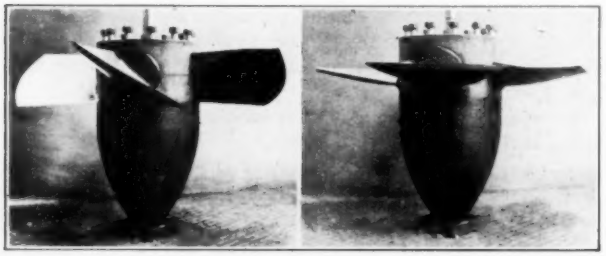

Fig. 1 Kaplan Turbine Runner
A—Blades in position for maximum load or quantity. B—Blades in position for minimum load or quantity.)

Moody, the Cammerer, and the Staufer formulas for predicting the maximum efficiency which may be expected of a full-scale turbine from a model test. These formulas are:

1 *Moody formula:*

$$E = 1 - (1 - e)\left(\frac{d}{D}\right)^{1/4}\left(\frac{h}{H}\right)^{1/10}$$

2 *Cammerer formula:*

$$E = 1 - (1 - e)\frac{1.4 + \sqrt{\frac{1}{D}}}{1.4 + \sqrt{\frac{1}{d}}}$$

Where E = maximum efficiency of the full-scale turbine
e = maximum efficiency of the model
D = diameter of the full-scale turbine
d = diameter of the model
H = head on the full-scale turbine
h = head on the model turbine.

In the Aufkirchen plant (Germany) the Cammerer formula gave a predicted efficiency of 91.1 per cent and the Moody formula of 93.7 per cent. The actual acceptance test showed an efficiency of 92.6 per cent, or between the two, indicating that the Moody formula gives results a little too high and the Cammerer formula a little too low. There also has been published recently another formula known after the man who proposed it as the Staufer formula. It is exactly the same as the Moody formula except the exponent for the ratio of heads is $^1/_8$ instead of $^1/_{10}$. In the case of the Aufkirchen plant this formula would give still higher results than the Moody formula. The amount of data at hand does not seem to warrant making a differentiation between an exponent of $^1/_{10}$ and $^1/_8$.

Draft-Tube Research

In many of the European hydraulic laboratories one finds that extensive research either has been made or is in process on draft tubes. All sorts, sizes, and shapes seem to have been tried, and the consensus of opinion seems to be that no one type of draft tube can claim superiority over others in all cases. The selection is dependent upon many factors, and if a maximum overall efficiency is to be obtained, the draft tube must be designed with the turbine runner.

Cavitation

Researches on the subject of cavitation are now in progress in several hydraulic laboratories in Europe. The foremost contributors to this work seem to be Professors Foettinger, of Berlin; Dahl, of Sweden; Oesterlen, of Hanover; and Thoma, of Munich.

Cavitation, including its prediction, prevention, or elimination, is today the foremost problem in the field of hydraulic-turbine design, and that laboratory which is not equipped to carry on research in this field is soon to find itself outclassed by its competitors. As pointed out, the chief means of making these studies is at present the visual one. The cheapest and perhaps most effective method of studying cavitation is the use of the stroboscope upon models, and the stroborama is a finer, better instrument for this work.

There are several theories as to the cause of cavitation which will be found discussed in "Turbines and the Cavitation Problem," by Elov Englessan, *Canadian Engineer*, April 13, 1916. The Swedes seem to have made the most rapid strides in finding metals that will resist cavitation, but the real problem is to find a method of eliminating it where high-speed Kaplan and propeller runners are used. This is necessary because cavitation very materially reduces efficiency.

Probably the best-equipped cavitation laboratories in the

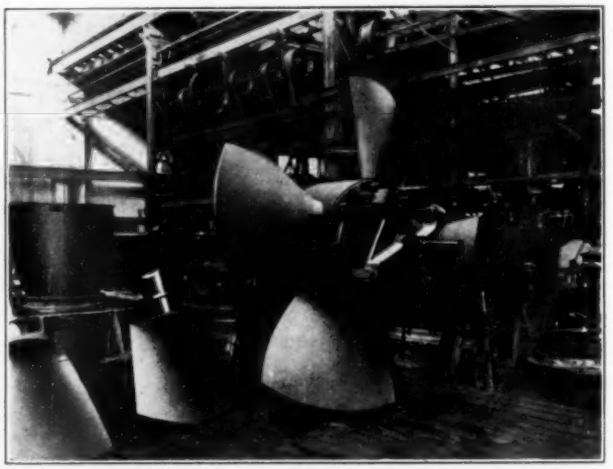

Fig. 2 Kaplan Turbine Runner, by J. M. Voith, Heidenheim, Germany
(Mechanism is shown for moving the blades of the runner while it is in motion.)

world today are those at Kristinehamn and the University of Stockholm, Sweden; J. M. Voith's in Heidenheim, Germany, and the Escher Wyss laboratory now under construction at Zurich, Switzerland.

Two European Turbines

There are two types of turbines that are distinctly European. Not only have they been developed in European laboratories,

but as yet they have not been used in America. They are the Kaplan and the Banki turbines.

The Kaplan turbine, invented by Professor Kaplan, of Brunn, about 1910, is a high-specific-speed propeller type of turbine, the propeller blades of which may be adjusted externally by means of a servomotor actuated by the governor while the turbine is in motion (Fig. 2). The Kaplan turbine has been used for heads up to 56 ft., as at the Wiesenberg plant in Czechoslovakia, and Mr. Elov Englessan, chief designer for Verkstaden, Kristinehamn, Sweden, is the authority for the statement that "50 feet can be regarded as a safe upper limit for the present, but for a head of this magnitude both the specific speed and the turbine has been written by Prof. Viktor Kaplan in "Die Entwicklung des Kaplan-Laufrades," 1927–1928, Wasserkraft Jahrbuch, pp. 414–424. Here it is shown that the Kaplan turbine was conceived as a propeller turbine, but gradually evolved into a propeller turbine with movable blades.

The Kaplan turbine has the characteristics of propeller-type turbines, and in addition it has the advantage that its blades can be moved so that it at all times operates with its blades in a position of maximum efficiency, and therefore it gives a much higher efficiency at partial loads and overloads than does either the Francis or the simple propeller-type turbine (Figs. 3 and 4). This has been clearly shown by a number of European experi-

suction height must be low in order to avoid the danger of cavitation." (See *Canadian Engineer*, January 5 and 12, 1926.)

There are about 150 Kaplan turbines manufactured by European firms in actual use, having an installed capacity of over 300,000 hp. That American engineers traveling in foreign countries may know of the plants using Kaplan turbines and perhaps visit them and obtain first-hand information of their successful operation, a list of Kaplan turbine plants is given in Table 2.

This is by no means a complete list of Kaplan turbines in use in Europe, and it is only a very partial list of those made by European manufacturers for it omits most of those manufactured by Verkstaden, Kristinehamn, Sweden, and the Riva Construction Company of Milan, Italy.

A recent account of the historical development of the Kaplan menters and writers. The experience of the Escher Wyss Company is shown in Fig. 5; that of the Riva Construction Company, Milan, Italy, in Fig. 6; that of Voith in Fig. 7; and that of Kristinehamn, Verkstaden, in Fig. 8. It will be noticed that the experiences of these companies are almost identical. The flat efficiency curve of the Kaplan turbine means economy of water. Thus the ideal field for the Kaplan turbine is for low heads below 50 ft. where economy of water is essential. It will also be noticed that another advantage of the Kaplan turbine is that for the same efficiency it will carry about 50 per cent overload while the propeller type of turbine will carry only about 5 to 10 per cent and the Francis from 10 to 15 per cent. The fewer the number of units the more important is the Kaplan turbine in its field. Mr. Englessan, in "Kaplan and Propeller Turbines Com-

pared" (*Canadian Engineer*, January 5 and 12, 1926), has given an excellent example of the water savings that may be obtained by the Kaplan turbine.

On account of its slower speed there is seldom any advantage in installing a Francis turbine for low heads because of the increased cost of the generator. Therefore the Kaplan's real competitor is the propeller-type turbine. Combinations of propeller and Kaplan turbines frequently are used in Europe, because, on account of their higher partial-load efficiency, the number of units can be reduced in many cases by the use of Kaplan turbines.

The size of the Kaplan turbine is limited by the size to which

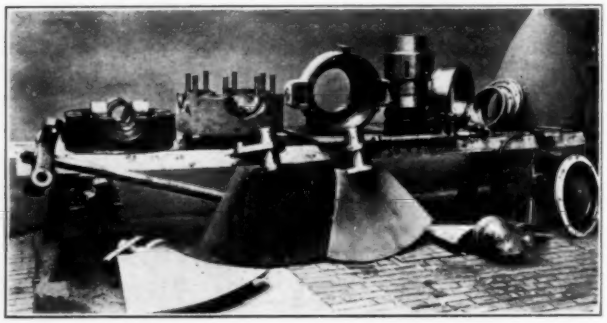

FIG. 3 KNOCKDOWN VIEW OF KAPLAN TURBINE RUNNER
(Showing small number of parts.)

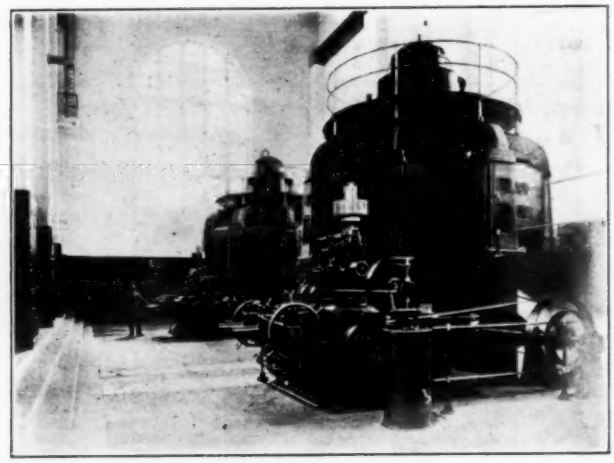

FIG. 4 POWER PLANT AT GRATWEIN, WITH TWO KAPLAN TURBINES BY J. M. VOITH
(These turbines each deliver 3540 hp. under a head of 27.9 ft. with 1380 cu. ft. per sec. of water, and operate at 167 r.p.m.)

the hub can be made, and this in turn seems to be limited by the size of the railway car for transporting it, which limits the hub to about 26 ft. diameter. As yet no Kaplan turbine has been constructed of that size.

The chief disadvantages of the Kaplan turbines are, first, their initial cost, which varies with the size of the unit from 15 to 75 per cent more than a propeller-type turbine; second, the fact that they are more complicated and therefore susceptible to more mechanical troubles; third, that they consume more oil than do propeller turbines. The author found in Europe that these objections were theoretical rather than practical and that the Kaplan turbines of today are giving satisfactory service. The savings in water and generator costs usually offset the increase in Kaplan turbine costs. The Kaplan turbine has largely passed the experimental stage; its mechanical operation seems from all reports to be as satisfactory as that of any other type of turbine. The leakage or loss of oil has not been found to be excessive or expensive. Therefore, considering these facts, it may be expected that the Kaplan turbine will soon make its initial appearance in American practice.

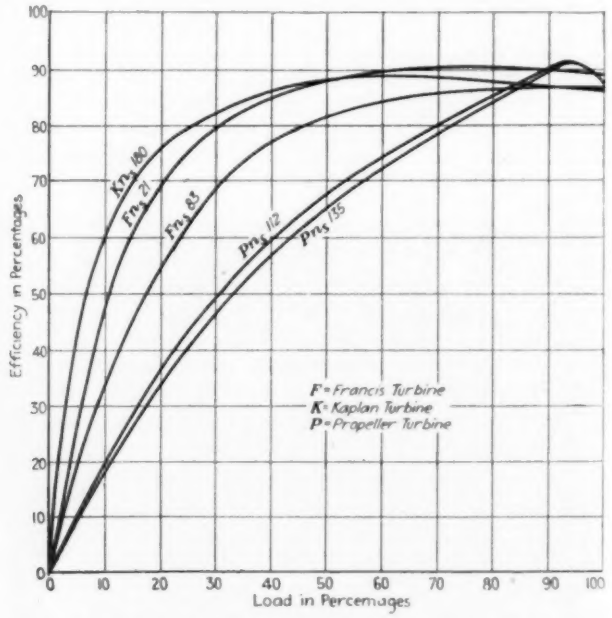
THE BANKI TURBINE

The second European turbine that has quite novel features is the Banki turbine (Figs. 9, 10, and 11). This turbine has not received the consideration it deserves, primarily because it is not adaptable to extremely large units. Then no doubt the fact that it is of Hungarian origin has delayed its development, because the Hungarians have not been as successful as the Germans and Americans in commercializing their ideas. There are, however, today, according to Mr. Banki, of Budapest, the son of the inventor of the turbine, more than a thousand of these turbines in actual use.

BANKI TURBINE THEORY

The theory of the Banki turbine was developed by its inventor, Prof. Donat Banki, at the Hungarian Technical University, where Professor Banki taught for many years prior to his death. (See "Neue Wasserturbine," von Donat Banki, Druck des Franklin Verein.)

The Banki turbine, as shown in Fig. 9, has a head acting on the point A of h_1, and the velocity coefficient of the nozzle is φ.



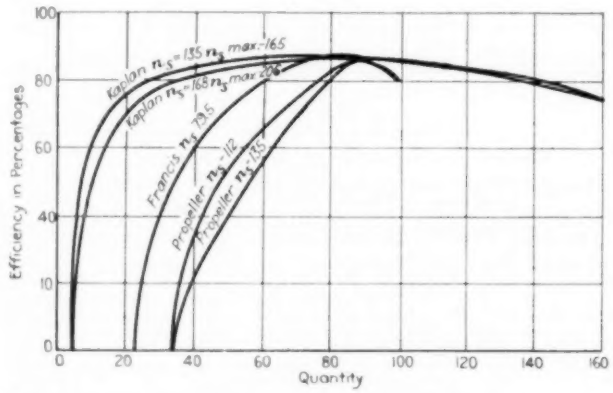


FIG. 5 COMPARATIVE EFFICIENCY CURVES OF PROPELLER, FRANCIS, AND KAPLAN TURBINES
(As obtained by Escher Wyss Company, Zurich, Switzerland.)

The spouting velocity, or the absolute velocity with which the water strikes the turbine, will be

$$c_1 = \varphi \sqrt{2gh_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

If the angle of the bucket at A is α_1 with the tangent at that point and the velocity of the runner is u_1, by the usual triangle law the relative velocity will be w_1, making an angle β with the tangent at A. If it is assumed that the water flows through the runner with undiminished velocity, it will leave B when it has reached a position b with a relative velocity w'_2, and a direction β'_2 with the tangent at B. The velocity of the runner at

this point has been reduced (because of the shorter radius) to u_2, and the absolute velocity is found by the same triangular relationship to be c'_2. The absolute path of the water through the bucket is A-b, and the water leaving point b travels in a stream line, again entering the runner at point C. The path b-C when viewed in the small glass-encased model in the Deutscher Museum at Munich, Germany, appears to be a straight line. If this is assumed, the water will follow a path b-C and enter the bucket of the runner again at C with a velocity $c'_1 = c'_2$ and in a direction

F.G. 6 Comparative Efficiency Curves of Propeller, Francis, and Kaplan Turbines

(As obtained by the Riva Construction Company, Milan, Italy.)

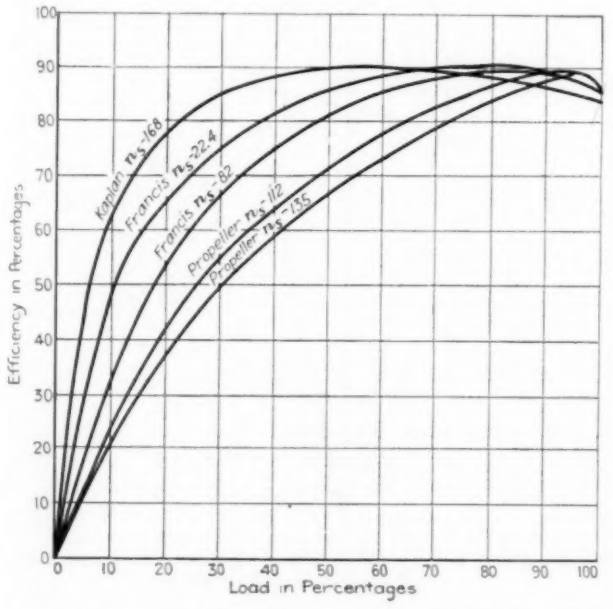

Fig. 7 Comparative Efficiency Curves of Propeller, Francis, and Kaplan Turbines

(As obtained by J. M. Voith Company, Heidenheim, Germany.)

such that $\alpha'_1 = \alpha'_2$; and since $\beta'_1 = \beta'_2$ and $\beta_2 = \beta_1$ (because of the construction of buckets), the construction of the velocity triangle gives a final absolute velocity of discharge of c_2 in such a direction as to form with the tangent at point D the angle α_2.

If this theory were correct, the stream line through the turbine would be as shown in Fig. 10-A. Actually, however, visual experiment shows that the water behaves approximately as shown in Fig. 10-B.

If L = power in foot-pounds per second
Q = quantity in cubic feet per second
γ = weight of a cubic foot of water (62.4 lb.)
g = gravitational constant (32.2)

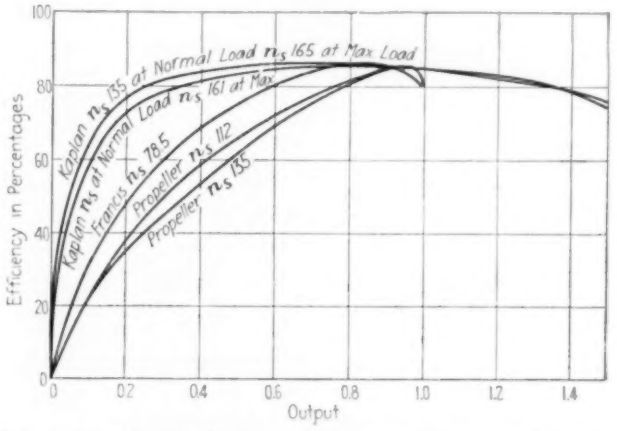

Fig. 8 Comparative Efficiency Curves of Propeller, Francis, and Kaplan Turbines

(As obtained by Kristinehamn, Verkstaden, Sweden.)

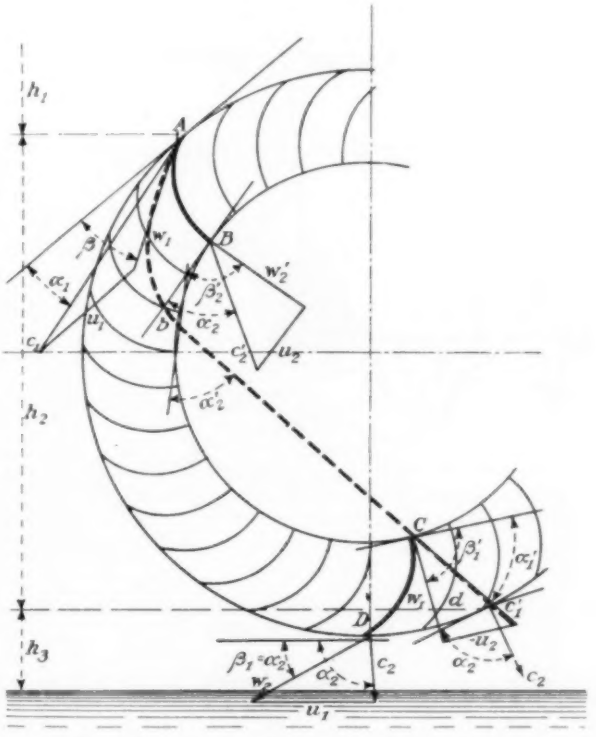

Fig. 9 Diagrammatic Sketch of a Banki Turbine

From the foregoing relationships it can be seen that

$$L = \frac{Q\gamma}{g}(c_1 \cos \alpha_1 + c_2 \cos \alpha_2)u_1 \quad \ldots\ldots\ldots\ldots [2]$$

and from the discharge triangle this same thing may be expressed in the form

$$c_2 \cos \alpha_2 = w_2 \cos \beta_2 - u_1 \quad \ldots\ldots\ldots\ldots [3]$$

and by use of the velocity coefficients ψ and φ_1, w_2 may be expressed

$$w_2 = \psi w_1 + \varphi' \sqrt{2gh_2} \quad \ldots\ldots [4]$$

and from the entrance triangle relationship

$$w_1 = \frac{c_1 \cos \alpha_1 - u_1}{\cos \beta_1} \quad \ldots\ldots [5]$$

If these are substituted in Equation [2] we have

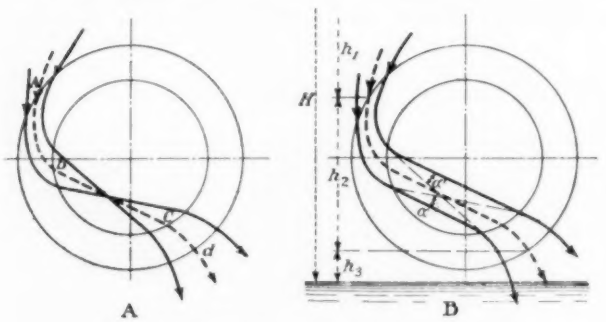

FIG. 10 THE CROSS-FLOW BANKI TURBINE
(A—Theoretical way the water travels through the turbine parts. B—Actual way the water travels.)

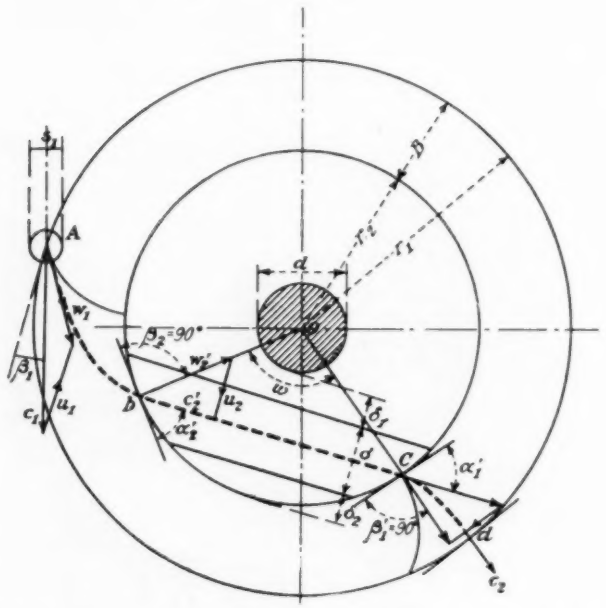

FIG. 11 BANKI TURBINE; GEOMETRICAL FIGURE FOR DETERMINING DESIGN OF RUNNER

$$L = \frac{Q\gamma}{g}\left[(c_1 \cos \alpha_1 - u_1)\left(1 + \psi \frac{\cos \beta_2}{\cos \beta_1}\right) + \varphi' \sqrt{2gh_2} \cos \beta_2\right] u_1 \quad \ldots\ldots [6]$$

The total power input is $Q\gamma h_1$, hence the efficiency would be

$$E = \frac{L}{Q\gamma h_1} = \frac{L}{Q\gamma \dfrac{c_1^2}{\varphi'^2 2g}} = 2\varphi^2 \left(1 + \psi \frac{\cos \beta_2}{\cos \beta_1}\right)\left(\cos \alpha_1 - \frac{u_1}{c_1}\right)\frac{u_1}{c_1} \quad \ldots\ldots [7]$$

For the case where $\beta_2 = \beta_1$

$$E = 2\varphi^2 (1 + \psi)\left(\cos \alpha_1 - \frac{u_1}{c_1}\right)\frac{u_1}{c_1} \quad \ldots\ldots [8]$$

To determine the point of maximum efficiency differentiate the efficiency with respect to the ratio $\frac{u_1}{c_1}$, and placing it equal to zero we obtain

$$\frac{u_1}{c_1} = \frac{\cos \alpha_1}{2} \quad \ldots\ldots [9]$$

Substituting this in Equation [8] gives a maximum efficiency

$$E \text{ (max)} = \frac{1}{2}\varphi^2 (1 + \psi) \cos^2 \alpha_1 \quad \ldots\ldots [10]$$

Professor Banki also showed that the angle should be of the order of 16 deg. and the angle β should be around 90 deg.

The radial length of the vanes B (see Fig. 12) was found to be best under the conditions

$$B = 0.17\, D_1 \quad \ldots\ldots [11]$$

where D_1 is the external diameter of the runner and

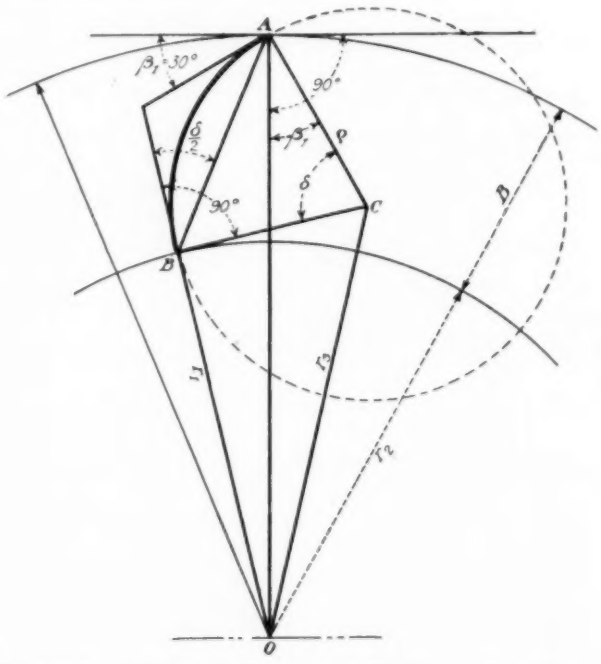

FIG. 12 BANKI TURBINE; GEOMETRICAL FIGURE FOR DETERMINING DESIGN OF RUNNER PARTS

$$D_1 = \frac{72.2\sqrt{H}}{n} \quad \ldots\ldots [12]$$

where D_1 and H_1 the head, are in feet and n is r.p.m. The design is a very simple matter because the vanes are nothing more complex than the arc of a circle (see Fig. 12) whose radius is of the order

$$r_3 = 0.326 r_2 \quad \ldots\ldots [13]$$

The number of vanes is determined by the thickness of the entering stream, which in turn determines the thickness of the water stream passing from the first set of vanes to the second (Fig. 11).

Thus σ must not be larger than

$$\sigma = 1.89\, s_1 \quad [14]$$

and δ_2 must lie between the range

$$\delta_2 = 0.0606\, D_1 \text{ and } 0.0369\, D_1 \quad [15]$$

The radial length of the Banki turbine lies between the limits

$$b = 0.263\, n\, \frac{Q}{H} \text{ and } 0.197\, n\, \frac{Q}{H} \quad [16]$$

where b and H are in feet and Q in cubic feet per second.

Thus it is seen that the design of a Banki turbine is extremely

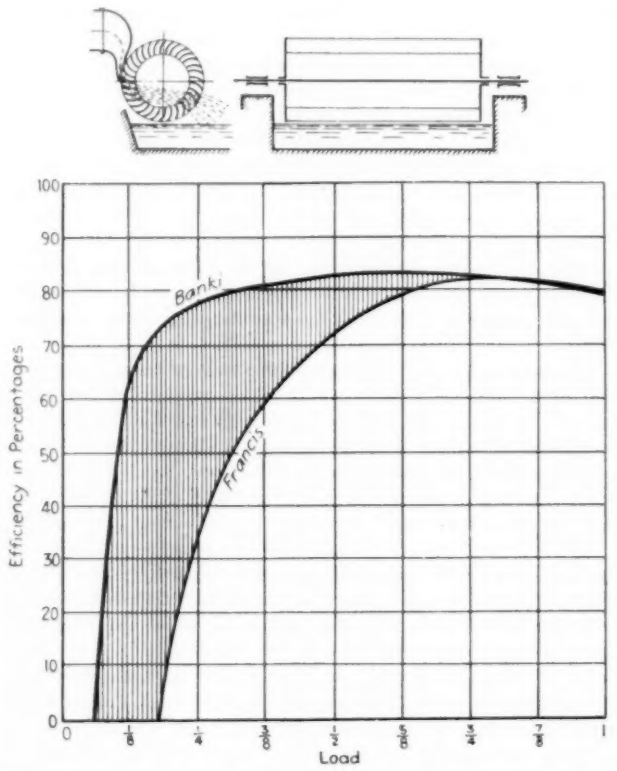

FIG. 13 COMPARATIVE EFFICIENCY CURVES OF BANKI AND FRANCIS TURBINES

simple as are also its construction and manufacture. The chief advantages claimed for this turbine are:

First, its high efficiency; for even very small units the efficiency is over 85 per cent (see Fig. 13).

Second, for heads around 17 ft., the Banki turbine will develop a speed of 127 r.p.m., whereas an overshot wheel under the same head would develop but 17 r.p.m.

Third, for a head of about 3 ft. and 21 cu. ft. per sec., a paddle wheel would not only have a low efficiency and be very large (about 21 ft. diameter), but would run at 1.36 r.p.m., while the Banki turbine under the same conditions would be 3 ft. diameter and operate at about 41 r.p.m.

Fourth, an undershot wheel operating under a head of 5 ft. and about 35 cu. ft. per sec. would run 9 r.p.m., while the Banki turbine would be smaller, would have a higher efficiency, and would run 42 r.p.m.

Fifth, in comparison with the Pelton or impulse wheel, using two nozzles, Professor Banki has shown that the Banki turbine would have a specific speed of twice the impulse wheel with two nozzles.

Sixth, the Banki turbine fills the specific speed gap between the Pelton impulse wheel and the Francis turbine; that is, it has a specific speed of from 6 to 20 English units.

Professor Banki made no comparisons with his turbine and the propeller type, because at the time his invention was made, the propeller turbine was not used and very little known. How-

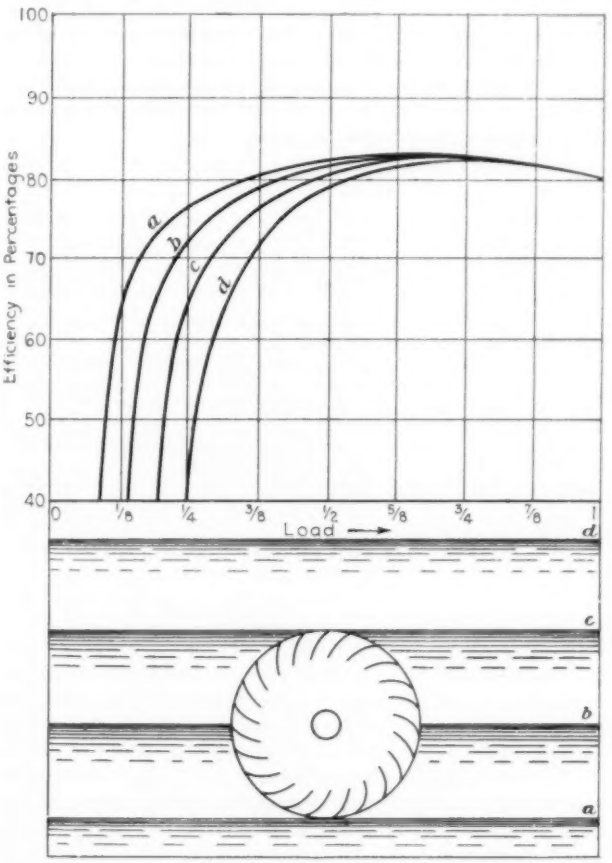

FIG. 14 SHOWING THE EFFECT OF SUBMERGENCE UPON THE BANKI TURBINE

ever, if we compare the Banki turbine mentioned with the propeller unit at Allenstein, which operates under a head of 18 ft. and a quantity of 350 cu. ft. per sec., delivering 608 hp. at 187 r.p.m., we find that its specific speed is

$$\frac{187 \times \sqrt{608}}{18\ (18)^{1/4}} = \frac{187 \times 24.5}{18 \times 2.06} = 125$$

while the Banki turbine would be lower, or about 70.

Thus it is seen that the Banki turbine does not compare so favorably with the modern propeller or Kaplan turbine from the viewpoint of speed. However, in simplicity of construction and cheapness for very small units, it is undoubtedly superior, and as shown in Fig. 13 the Banki turbine has a much higher part-load efficiency than either the Francis or the propeller type of turbine.

Fig. 14 shows that the Banki turbine is not materially affected by water submergence. Its speed regulation problems are almost the same as those of the impulse wheel, which can be and are satisfactorily solved.

The chief field for the Banki turbine seems to be where most of them are now used; namely, in small isolated farms or resort plants.

More attention could be given to this field in America although almost all American manufacturers have stock units which they sell to meet this demand. However, the cost of these units is frequently beyond the means of the farmer, and consequently there are today many gas engines in use in isolated mountain farms where small hydraulic power plants could be installed.

These European hydraulic-turbine researches are given, not because they are superior to American methods of solving our hydraulic problems, but because they are different and therefore may offer suggestions to engineers for study and research, the only road to engineering progress.

Discussion

George A. Orrok.[2] A paper of this kind is most welcome, combining, as it does, much information on hydraulic research as well as statistics on two very interesting types of water wheels which have not been exploited to any extent in America. While the Kaplan design has been known to hydraulic engineers for some time, the Banki design is comparatively new and fits in a distinctive place where formerly the free deviation turbine was the only occupant. The Kaplan turbine is at the further end of the scheme, and with its neighbors of the propeller type has greatly increased the limits of permissible specific speed. The extensive development of low-head plants, particularly in the larger sizes, has been made practical by the use of the propeller and Kaplan designs, and heads as low as 7 to 8 ft. under proper conditions may now be utilized with good economic results.

We might be inclined to differ from Mr. Van Leer in his characterization of American contributions as the "result of a few months' thought and experimentation" when we remember that the Holyoke testing flume has been in continuous existence for more than 70 years and that its results are of an "acknowledged excellence." It is of course true that the stock wheel, built in quantity and sold by the pound, has had its greatest development in this country, but I think it is also true that our designers, with the aid of Holyoke and their own laboratories, have produced wheels of at least equal excellence when compared with the product of any European manufacturer. And I believe it is also true that our earlier hydraulic development would not have taken place were it not for the stock wheel. This, however, is ancient history.

There are many hydraulic problems still before us today which must be solved, and, as Mr. Van Leer intimates, the hydraulic laboratory and the research engineer must find the solution for us if we would keep in the vanguard of progress.

[2] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

Byron E. White.[3] It is perhaps unfortunate that Professor Van Leer's paper, taken by itself, can conceivably lead to the impression that hydraulic laboratories are a peculiarly European institution, thus leaving the inference that we know little or nothing about the theory or practice of model experiments and the conduct of hydraulic laboratories in the United States.

From personal observation it is possible to state that there is at least one technical college laboratory in the United States which rather fully measures up to the standards of the European laboratories so well described by Mr. Van Leer. The Worcester Polytechnic Institute, at Chaffins, near Worcester, Mass., has a very complete and well-equipped laboratory, operated under the direction of Prof. C. M. Allen. At this laboratory there have been carried out many experiments on a large variety of hydraulic structures and equipment which have resulted in great improvements in design and operation as well as very substantial savings in the cost of construction.

The experiments on the Conowingo spillway and the inclined apron at the foot of it were conducted there. The experience with the full-sized dam and apron have confirmed the results of those experiments. Experiments have also recently been made on models of the upper and lower Fifteen Mile Falls developments of the New England Power Company on the Connecticut River, which were studies with the view to devising proper contours of the spillway discharge so as to prevent erosion of the sand and gravel river bank below the dam on the opposite side.

This laboratory also worked out the proper design and location of a baffle pier which was used in the spillway channel around the end of the hydraulic spill dam at the Sherman development of the New England Power Company and which successfully dissipated the energy of the water so that it did not erode the river bank opposite the discharge during periods of extreme high water.

The Alabama Power Company also has a very complete hydraulic laboratory operated under the direction of Mr. I. A. Winter, hydraulic engineer, in which several of the notable structures and devices of that company were tested, revised, and proved before construction.

At the October meeting in Philadelphia of the Hydraulic Power Committee of the National Electric Light Association, Mr. Winter showed a series of lantern slides and moving pictures of model tests and of the operation of the full-sized units corresponding thereto at a time of almost maximum flood, in which the correspondence of the tests and the actual results was extremely close.

Several other power companies, as well as colleges and universities and technical schools, maintain more or less completely equipped laboratories for the study of particular or general problems. These laboratories are really linear descendants of the early experiments of Mr. James B. Francis, Lowell, Mass., and of the still later Holyoke testing flume, at Holyoke, Mass., which was conducted for so many years by that distinguished hydraulician, Mr. Clemens Herschel.

It can be safely said that anyone desiring to have experiments on models carried out can entrust them to one or more of the several excellent hydraulic laboratories in the United States with the assurance that they will be carried out under the most competent supervision and that the results may be used with the greatest confidence.

I would like also to refer to the units at the Trenton Falls, N. Y., power house. With my colleague, Mr. William Monroe White, and Mr. H. A. Hageman, who was resident engineer during the construction of the plant from 1900 to 1902, it was

[3] General Engineer, Utica Gas and Electric Co., Utica, N. Y. Mem. A.S.M.E.

my privilege in November, 1928, to examine, both internally and externally, the first of the four 1700-horsepower units, which were the first of Mr. White's design, and to note that after 26 years of operation the original runner is still in place and has pitted but little.

As this is a cylinder-gate turbine, designed in 1902, its efficiency is naturally much below that of the turbines of this date. This and the three other machines are, however, used at times of high water, sometimes several weeks each year.

It is interesting to note the comparison as to pitting between these three turbines and three other machines installed in the same station about 10 years ago. The three latter have required the replacement of runners several times on account of pitting, and in every case we have found it necessary to weld the pitted areas at least once a year. I am wondering if the practice of running these new machines at part gate for extensive periods of time does not have something to do with the prevalence of and the extent of pitting. The old machines of 1902 had their point of best efficiency at full gate and were customarily operated at that point, and it is barely possible that it is for that reason that pitting and erosion of their runners have not been more pronounced.

CLEMENS HERSCHEL.[4] The last speaker was especially clear on the benefits of models in solving hydraulic problems. Of course, that is an old story in the United States. The predominant position of turbine wheels in the United States is largely due to experiments on models made in the Holyoke testing flume, which has been there a great many years—ever since the eighties of the last century. But there is a recent development in Europe, of which I have been informed lately, which I think will be of interest, and that is the work and construction, present and future, of what I will call the National Hydraulic Observatory of Germany, rather than attempt to translate the long name given it in Germany.

The point involved is that here is an investment already of about $350,000; and remember, this is in poor Germany, and $350,000 over in Germany is certainly equivalent to six or seven hundred thousand dollars here; and they purpose to bring it up to half a million dollars. The system to be followed is to experiment in full size; though they also can test the principle of similitudes, and then try to prove what is the law to pass from models to full size. You can see from this statement and from the amount of money involved that this is no small affair.

They have formed there a company, and they call it a stock company. The German Government, the Bavarian Government, and the principal power plants of Germany are stockholders, but they do not expect any dividends in the shape of money. They help to operate the plant by an annual contribution, and for dividends they only expect information from the results of tests that are being made.

That is something that it seems to me is new and is entirely applicable to this country. There is not the slightest doubt that the results of the work done there will be of the greatest interest. The man in charge, I am pleased to say, is a hydraulic engineer, not a philosopher or, to use a much-abused word, a scientist.

S. LOGAN KERR.[5] It is very interesting to have presented to American engineers a general summary of some of the recent developments in hydraulic-turbine design in Europe. The writer had the privilege of visiting a number of the plants described in Mr. Van Leer's paper and also of visiting laboratories of four of the leading water-wheel manufacturers in Europe.

[4] Consulting Engineer, New York, N. Y.

[5] Research Engineer, I. P. Morris Corp. and De La Vergne Mach. Co., Philadelphia, Pa. Assoc-Mem. A.S.M.E.

The European testing laboratories constructed by the manufacturing companies do not differ materially from those which have been built by American turbine manufacturers. However, one additional step which has been taken in Europe has been the development of the cavitation laboratory for experimentally studying the effect of draft head and its reaction upon the performance of the turbine.

There are two types of laboratories. One of these employs the turbine with a very long draft tube installed in a specially constructed tank with provision for adjusting either the head water or tail water, or both. By this means the performance of the units under different heads can be studied, and the performance under constant head but with different draft heads can also be determined. The other type of cavitation laboratory employs two pressure chambers connected through a centrifugal pump arranged in such a manner that the supply to the turbine is drawn from one tank, discharged into another, and then pumped from the second tank back to the first. The total pressure can be controlled and the suction on the turbine can be varied by controlling the pressures in the discharge tank, and the head on the turbine can be increased by varying the pressures in the two tanks in such a manner that the desired combination is secured.

It is interesting to note that the European manufacturers have experimentally confirmed the theoretic analysis developed by Mr. L. F. Moody dealing with the permissible draft head on the turbine.

The European engineers draw a very nice distinction between the various types of so-called propeller turbines. They define a propeller turbine as any water wheel of the general form of the marine propeller operating without a runner band. The Kaplan turbine, however, is designated as a propeller-type turbine in which the blades are adjusted automatically from the governor.

There is no doubt of the commercial success of both the propeller and Kaplan turbines in Europe. In this country, however, there has not been a demand for the adjustable-blade type of runner due to the great difference between the general plan of operation of our public utilities. In small low-head plants where the adjustable-blade propeller-type turbine would find its greatest application, it is possible to operate these plants for peak-load power and to divide them into a sufficiently large number of units so that they can be operated at approximately the maximum efficiency point.

When the demand comes from the American public utilities for the adjustable-blade type of units, together with their willingness to meet the increased cost of this type of turbine, American manufacturers will be ready and willing to meet the demand. Just now, however, the fixed-blade type of unit or turbines having manually adjusted blades meet the requirements.

GEORGE A. JESSOP.[6] The author offers a very valuable contribution to the available information concerning hydraulic-turbine practice. European developments are not generally followed as closely in this country as they should be to take advantage of the research continuously going on abroad. The data concerning the high-speed Kaplan turbine are of particular interest at the present time. In Europe it is the exception to use a high-specific-speed propeller-type turbine with fixed blades, almost all installations having the automatic adjustable-blade feature. In this way full use is made of the advantages of the Kaplan turbine. A study of this paper together with the references cited will show these advantages to be three in number:

1 High efficiency under normal operation

[6] Chief Engineer, S. Morgan Smith Co., York, Pa.

2 The same high efficiency under part load (part gate) where high efficiency is desired to conserve water and to obtain the maximum output from the available limited supply of water

3 Excess capacity under flood-water conditions.

That the engineers on this side of the Atlantic are aware of the economies to be obtained by the use of the governor-controlled adjustable-blade turbine is evident from the fact that a number of such installations are now being made and will very soon be in operation in this country and Canada.

Dr. Kaplan has had ten patents issued in this country which fully cover his inventions of the fixed- and adjustable-blade axial-flow turbines.

Exclusive rights under the United States patents have been granted to the S. Morgan Smith Company, who also have the rights for Canada.

Author's Closure

Sincere thanks are extended to Messrs. George A. Orrok, Byron E. White, Clemens Herschel, S. Logan Kerr, and others who contributed much to the interest evinced in the paper by their intelligent and constructive discussions.

In view of the fact that some of the gentlemen who discussed the paper voiced the sentiment that it might lead to the conclusion that European engineers and methods were superior to those of America, the author wishes to call attention to the closing paragraph of this paper which states:

"These European hydraulic-turbine researches are given, not because they are superior to American methods of solving our hydraulic problems, but because they are different and therefore may offer suggestions to engineers for study and research, the only road to engineering progress."

Also, he wishes to again emphasize that this paper deals with "Some Interesting European Hydraulic Turbine Research." Under such a title it did not seem appropriate to laud American hydraulic engineers whose works are known to every college boy studying hydraulics. Such names as Mills, Francis, Pelton, Worthington, Gibson, Herschel, Freeman, Moody, are secure so far as the history of our hydraulic arts is concerned.

Since this question has been brought up, it would perhaps be of interest to note that the author found that Messrs. Herschel, Freeman, Moody, contemporary American engineers, were exceedingly well known in Europe; in fact, there was not a hydraulic laboratory or European manufacturer visited in Europe by the author where at least one of these names was not known, and in every instance these gentlemen were spoken of in the highest terms of praise and respect.

Perhaps the writer has been in charge of a hydraulic laboratory so long and has become so inseparably bound to the movement to secure a national hydraulic research laboratory that every paper he writes is looked upon as propaganda to that end. However, to accomplish this purpose, it is not necessary to deprecate any existing hydraulic laboratory. The excellent hydraulic laboratory at Worcester Polytechnic Institute and the one belonging to the Alabama Power Company are both described in "Hydraulic Laboratory Practice," a monumental hydraulic contribution, edited by John R. Freeman and published by the American Society of Mechanical Engineers. There are many experiments which may be carried on in these laboratories, and there are some for which they are not at present equipped. It is hoped and expected that they will continue to make valuable contributions to hydraulic engineering.

It was most gratifying to have the distinguished inventor of the venturi meter, Mr. Clemens Herschel, present at the meeting of the Hydraulic Division, and to hear him call attention in such an interesting manner to one of Germany's unique institutions. The organization to which he referred is Forschungsinstitut fur Wasserbau und Wasserkraft (the Research Institute for Hydraulic and Hydro-Electric Structures), near Munich, Germany, which is under the direction of Dr. Otto Kirschmer. This institute was described in the August, 1928, issue of *Mechanical Engineering*.

The excellent discussion by Mr. S. Logan Kerr needs no comment; it speaks for itself, and the author concurs in the points set forth.

Flow in Pipes

By MICHAEL D. AISENSTEIN,[1] OAKLAND, CALIF.

THE purpose of this paper is to present general formulas for the frictional resistance in straight circular pipes based on the experiments of different authorities and to show their application to the solution of different problems in connection with divided flow and accelerated streamline flow.

The following symbols and nomenclature are used:

t	=	time in seconds
v	=	velocity of flow in feet per second
L	=	pipe length in feet
h	=	head in feet
ν	=	kinematic viscosity in English units
μ	=	absolute viscosity in English units
T	=	viscosity in Saybolt seconds universal
w	=	weight in pounds per cubic foot
ρ	=	density in pounds per cubic foot
a	=	area in square feet
D	=	diameter in inches
d	=	diameter in feet
p	=	pressure in pounds per square inch
A.P.I.	=	American Petroleum Institute gravity
g	=	gravitational constant 32.2
vd/ν	=	Reynolds' criterion
Q	=	cubic feet per second
G	=	gallons per minute
B	=	barrels per hour
M	=	mass
$s.g.$	=	specific gravity

There are two kinds of motion of a particle of liquid, one in which the particle has a steady streamline motion and the other where the motion is unsteady accompanied by eddies.

For circular straight pipes the type of flow is determined by the Reynolds' criterion vd/ν. For values of vd/ν less than 2000 a streamline flow takes place; for vd/ν between 2000 and 3000 there is a break in the flow, and for vd/ν from 3000 up a turbulent flow takes place.

In a streamline flow the streams of fluid are symmetrical on both sides of a symmetrical obstruction (Fig. 1*a*) as the stabilizing effect of viscosity is greater than the effect of inertia forces of fluid particles. Consequently the roughness of the walls of the conduit has little effect on the flow. The velocity is very small near the walls increasing gradually toward the center. (Fig. 2.)

The ratio of the average velocity to the maximum velocity is approximately equal to 0.5. The velocity radius equation is that of a parabola

$$v = \frac{p}{4\mu}(r_0^2 - r^2) \qquad [1]$$

The turbulent flow is the most common in engineering practice. In a turbulent flow the velocity is of such a value that the inertia forces dominate the stabilizing effect of the viscosity with resulting eddies. It is evident that the roughness of the walls of the conduit increases the formation of the eddies. The average velocity is about 85 per cent of the maximum velocity.

[1] Chief Engineer, Pump Division, United Iron Works. Jun. A.S.M.E.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., December 3 to 7, 1928, of The American Society of Mechanical Engineers.

Friction Formulas for Streamline and Turbulent Flow

Next let us derive the general formulas for the friction drop in circular straight pipes for both types of flow.

It was found experimentally that the resistance to flow in a circular pipe is a function of some power of the diameter d in feet, length of the pipe L in feet, mean velocity of the flow v in feet per second, absolute viscosity μ in foot-poundal-second units, density ρ of the fluid in pounds per cubic foot, and depends on the surface condition of the pipe; therefore we may write,

$$p = Kd^x L^m v^n \mu^y \rho^z \qquad [2]$$

where p is the pressure in pounds per square foot at two points L feet apart along the pipe and K a dimensionless constant. The surface condition of the interior of the pipe does not enter

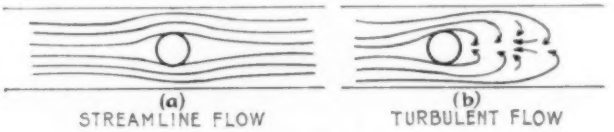

Fig. 1

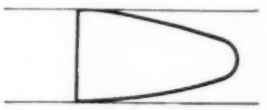

Fig. 2

Fig. 3

the equation and will be taken up later. Using the principle of dynamic similarity which is based on representation of force in terms of mass and acceleration, it is necessary that all terms in any equation having a physical significance have identical dimensions. Writing down for convenience the following table:

Quantity	Dimensions
Length	L
Time	T
Mass	M
Linear speed	LT^{-1}
Acceleration	LT^{-2}
Force	MLT^{-2}
Density	ML^{-3}
Viscosity	$ML^{-1}T^{-1}$
K	Constant, no dimensions.

Equation [2] may be rewritten

$$\frac{M}{LT^2} = L^x \left(\frac{M}{LT}\right)^y \left(\frac{M}{L^3}\right)^z \left(\frac{L}{T}\right)^n L^m \qquad [3]$$

Since the experiments indicate that the resistance to flow is, other things being equal, directly proportional to length, we can assume that m is equal to unity. Multiplying out Equation [3] and making $m = 1$

$$ML^{-1}T^{-2} = M^{z+y} L^{x-y-3z+n+1} T^{-y-n} \qquad [4]$$

According to the theory of homogeneity the dimensions on both sides of an equation in mechanics should be the same, therefore, to satisfy Equation [4],

$$x - y - 3z + n + 1 = -1$$

$$z + y = 1$$
$$-y - n = -2$$

solving these three equations for x, y, and z we have

$$x = n - 3$$
$$y = 2 - n$$
$$z = n - 1$$

substituting these values of x, y, and z in Equation [2] we have

$$p = KLd^{n-3}v^n\mu^{2-n}\rho^{n-1}$$

or because

$$p = h_f\rho g$$
$$h_f\rho g = KLd^{n-3}v^n\mu^{2-n}\rho^{n-1}$$

calling $K = \frac{K_0}{2}$ we have

$$h_f = K_0\frac{L}{d}\frac{v^2}{2g} \times \frac{v^{n-2}d^{n-2}}{\frac{\mu^{n-2}}{\rho^{n-2}}} \quad \text{.....[5]}$$

or in general

$$h_f = \frac{L}{d}\frac{v^2}{2g}\phi\left(\frac{vd}{\nu}\right) \quad \text{.....[6]}$$

for streamline flow, that is, when

$$\frac{vd}{\nu} < 2000$$

the coefficient $f = \phi\left(\frac{vd}{\nu}\right)$ was found by Poiseuille to vary with vd/ν as a rectangular hyperbola and to satisfy an equation (Fig. 4).

$$\phi\left(\frac{vd}{\nu}\right) = \frac{64}{\frac{vd}{\nu}} \quad \text{.....[7]}$$

Substituting in Equation [6] we obtain a formula for drop in head due to frictional resistance for streamline flow

$$h_f = \frac{64}{2g}\frac{L}{d^2}v\nu \quad \text{.....[I]}$$

Many experiments have been carried out to determine the friction coefficient in the turbulent region of flow. Since the roughness of the interior surface of the pipe has a great effect on the friction resistance in the turbulent type of flow, the results vary widely and many formulas have been devised to satisfy the different experimental results. From available data of different authorities the values of f and vd/ν were computed and plotted (Fig. 4).

An average curve was drawn by the author and the relation between f and vd/ν was expressed by an equation

$$f = \frac{0.167}{\left(\frac{vd}{\nu}\right)^{0.170}} \quad \text{.....[8]}$$

This equation will hold for so-called "commercially smooth" pipe. Substituting the value of f from Equation [8] in Equation [6] we obtain a formula for drop in head due to frictional resistance in the region of turbulent flow.

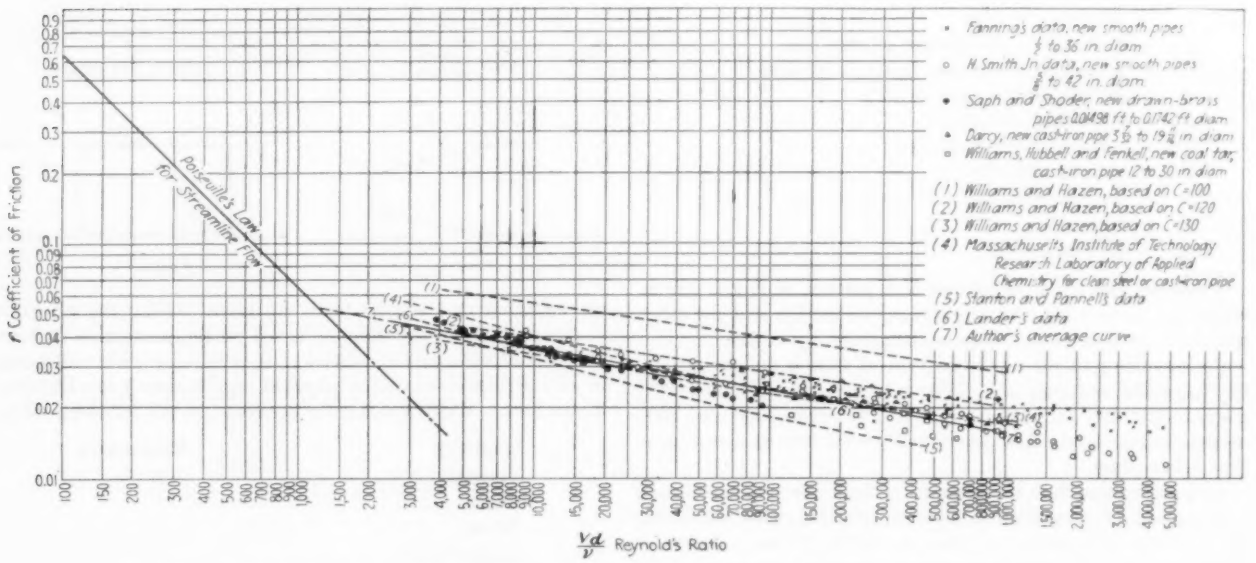

FIG. 4 RELATION BETWEEN f AND vd/ν BASED ON EXPERIMENTAL DATA OF AUTHORITIES NOTED

$$h_f = \frac{0.167}{\left(\frac{vd}{\nu}\right)^{0.170}}\frac{L}{d}\frac{v^2}{2g} \quad \text{.....[II]}$$

or

$$h_f = 0.167\,\nu^{0.170}\frac{L}{d^{1.170}}\frac{v^{1.830}}{2g} \quad \text{.....[III]}$$

in case of water having kinematic viscosity of 0.00001077 at 68 deg. fahr.

$$h_f = 0.0239\frac{L}{d^{1.170}}\frac{v^{1.830}}{2g} \quad \text{.....[IIIa]}$$

Inspecting Equations [I] and [II] we see that viscosity is a material factor in the friction drop in a region of streamline flow, and that it has a relatively small effect in a region of turbulent flow. There is an advantage in heating a viscous oil in the streamline region, which results in decrease of viscosity. In the streamline region the frictional resistance varies directly with

the viscosity and any change in viscosity will have a marked effect on frictional resistance. Since in turbulent flow the viscosity is raised to the 0.17 power, heating of the oil will not be very effective in so far as reduction of the frictional resistance is concerned.

Since there is no standard roughness and there is no way to measure it, no formula can be given to determine the coefficient of roughness. The friction drop for turbulent flow for a rough pipe is increased according to judgment. In general the effect of roughness diminishes with increase of pipe diameter. Roughness changes the slope of the f-$\frac{vd}{\nu}$ curve with a consequent increase of the exponent n in Equation [5].

Equations [I] and [II] may be rewritten for practical use as follows:

For streamline flow $vd/\nu < 2000$

$$h_f = 143200 \frac{v\nu}{D^2} \quad \text{ft. per 1000 ft. of pipe} \quad [9]$$

$$h_f = 26250000 \frac{Q\nu}{D^4} \quad \text{ft. per 1000 ft. of pipe} \quad [10]$$

$$h_f = 58600 \frac{G\nu}{D^4} \quad \text{ft. per 1000 ft. of pipe} \quad [11]$$

$$h_f = 41000 \frac{B\nu}{D^4} \quad \text{ft. per 1000 ft. of pipe} \quad [12]$$

$$P = 994 \frac{v\mu}{D^2} \quad \text{lb. per sq. in. per 1000 ft. of pipe} \quad [13]$$

$$P = 182200 \frac{Q\mu}{D^4} \quad \text{lb. per sq. in. per 1000 ft. of pipe} \quad [14]$$

$$P = 406 \frac{G\mu}{D^4} \quad \text{lb. per sq. in. per 1000 ft. of pipe} \quad [15]$$

$$P = 284.1 \frac{B\mu}{D^4} \quad \text{lb. per sq. in. per 1000 ft. of pipe} \quad [16]$$

For turbulent flow $vd/\nu > 3000$

$$h_f = 47.4\, \nu^{0.170} \frac{v^{1.830}}{D^{1.170}} \quad \text{ft. per 1000 ft. of pipe} \quad [17]$$

$$h_f = 652000\, \nu^{0.170} \frac{Q^{1.830}}{D^{4.830}} \quad \text{ft. per 1000 ft. of pipe} \quad [18]$$

$$h_f = 9.23\, \nu^{0.170} \frac{G^{1.830}}{D^{4.830}} \quad \text{ft. per 1000 ft. of pipe} \quad [19]$$

$$h_f = 4.79\, \nu^{0.170} \frac{B^{1.830}}{D^{4.830}} \quad \text{ft. per 1000 ft. of pipe} \quad [20]$$

$$P = 0.329\, \nu^{0.170} \rho \frac{v^{1.830}}{D^{1.170}} \quad \text{lb. per sq. in. per 1000 ft. of pipe} \quad [21]$$

$$P = 4530\, \nu^{0.170} \rho \frac{Q^{1.830}}{D^{4.830}} \quad \text{lb. per sq. in. per 1000 ft. of pipe} \quad [22]$$

$$P = 0.0641\, \nu^{0.170} \rho \frac{G^{1.830}}{D^{4.830}} \quad \text{lb. per sq. in. per 1000 ft. of pipe} \quad [23]$$

$$P = 0.03325\, \nu^{0.170} \rho \frac{B^{1.830}}{D^{4.830}} \quad \text{lb. per sq. in. per 1000 ft. of pipe} \quad [24]$$

Divided Flow

If a pipe line is composed of several pipes of different diameters and lengths the problem is to determine the length of a single line of a given diameter equivalent to the combination of pipes.

The streamline and turbulent flows must be treated separately.

In case of streamline flow

$$h_f = \frac{64}{2g} \nu \frac{vL}{d^2}$$

Since

$$Q = \frac{\pi d^2}{4} v$$

we have, expressing v through Q

$$h_f = \frac{64}{2g} \times \frac{4}{\pi} \nu \frac{L}{d^4} Q = 1.265\, \nu \frac{LQ}{d^4}$$

or

$$Q = \frac{h_f d^4}{1.265 \nu L} \quad [25]$$

For divided flow

$$Q = Q_1 + Q_2 + Q_3 + \ldots\ldots$$

using the same fluid, ν is constant, and substituting Q from Equation [25]

$$\frac{h_f d^4}{1.265 \nu L} = \frac{h_f}{1.265 \nu} \left[\frac{d_1^4}{L_1} + \frac{d_2^4}{L_2} + \frac{d_3^4}{L_3} + \ldots\ldots \right]$$

solving for L

$$L = \frac{d^4}{\left[\frac{d_1^4}{L_1} + \frac{d_2^4}{L_2} + \frac{d_3^4}{L_3} + \ldots \right]} \quad [A]$$

The following cases may occur in practice:

1 Determine the length of a single line of a given diameter equivalent to a single line of different diameter and equal length.

2 Determine the length of a single line of a given diameter equivalent to a number of parallel lines of the same diameter and equal length.

3 Determine the length of a single line of a given diameter equivalent to a number of parallel lines of equal length but different diameters.

4 Determine the length of a single line of a given diameter equivalent to a number of parallel lines of different length but equal diameters.

5 Determine the length of a single line of a given diameter equivalent to a number of parallel lines of different length and diameter.

Case 1.

$$L = \left[\frac{d}{d_1} \right]^4 L_1 \quad [26]$$

Case 2.

$$L_1 = L_2 = L_3 = \ldots\ldots$$
$$d_1 = d_2 = d_3 = \ldots\ldots$$

$$L = \frac{L_1}{N} \left(\frac{d}{d_1} \right)^4 \quad [27]$$

Case 3.

$$L_1 = L_2 = L_3 = \ldots\ldots$$
$$d_1 \neq d_2 \neq d_3 \neq \ldots\ldots$$

$$L = L_1 \left[\frac{d^4}{d_1^4 + d_2^4 + d_3^4 + \ldots\ldots} \right] \quad [28]$$

Case 4. $L_1 \neq L_2 \neq L_3 \neq \ldots\ldots$

$d_1 = d_2 = d_3 = \ldots\ldots\ldots$

$$L = \left[\frac{d}{d_1}\right]^4 \frac{1}{\left[\frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3} + \ldots\right]} \quad \ldots\ldots\ldots [29]$$

Case 5. $L_1 \neq L_2 \neq L_3 \neq \ldots\ldots$

$d_1 \neq d_2 \neq d_3 \neq \ldots\ldots$

Use Equation [*A*]

In case of turbulent flow, solving Equation [III] for v

$$v = \left[\frac{2gh_f}{0.167\,\nu^{0.170}} \times \frac{d^{1.170}}{L}\right]^{\frac{1}{1.830}}$$

$$v = \left[\frac{2gh_f}{0.167\,\nu^{0.170}}\right]^{0.546} \times \frac{d^{0.638}}{L^{0.546}} \quad \ldots\ldots\ldots [30]$$

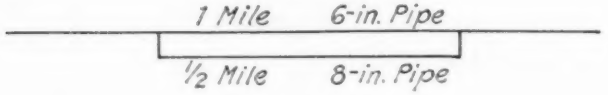

FIG. 5

since

$$Q = \frac{\pi d^2}{4} v$$

and expressing Equation [30] in terms of Q

$$Q = \frac{\pi}{4}\left(\frac{2gh_f}{0.167\,\nu^{0.170}}\right)^{0.546} \times \frac{d^{2.638}}{L^{0.546}} \quad \ldots\ldots\ldots [31]$$

Calling

$$\frac{\pi}{4}\left(\frac{2gh_f}{0.167\,\nu^{0.170}}\right)^{0.546} = K$$

$$Q = K\frac{d^{2.638}}{L^{0.546}} \quad \ldots\ldots\ldots [32]$$

If the flow is divided

$$Q = Q_1 + Q_2 + Q_3 + \ldots\ldots$$

Substituting Equation [32]

$$K\frac{d^{2.638}}{L^{0.546}} = K\left[\frac{d_1^{2.638}}{L_1^{0.546}} + \frac{d_2^{2.638}}{L_2^{0.546}} + \frac{d_3^{2.638}}{L_3^{0.546}} + \ldots\right]$$

Cancelling out K and solving for L

$$L = \left[\frac{d^{2.638}}{\frac{d_1^{2.638}}{L_1^{0.546}} + \frac{d_2^{2.638}}{L_2^{0.546}} + \frac{d_3^{2.638}}{L_3^{0.546}} + \ldots.}\right]^{1.830} \quad \ldots.[B]$$

Considering different cases in the same way as we have done for streamline flow we have:

Case 1. Equivalent length of a single pipe of equal length but different diameter

$$L = L_1\left[\frac{d}{d_1}\right]^{4.830} \quad \ldots\ldots\ldots [33]$$

Case 2. $L_1 = L_2 = L_3 = \ldots\ldots$

$d_1 = d_2 = d_3 = \ldots\ldots$

$$L = \frac{L_1}{N^{1.830}}\left[\frac{d}{d_1}\right]^{4.830} \quad \ldots\ldots\ldots [34]$$

Or

$$N = \left[\frac{L_1}{L}\right]^{0.545}\left[\frac{d}{d_1}\right]^{2.638} \quad \ldots\ldots\ldots [35]$$

where N is the number of parallel lines.

Case 3. $L_1 = L_2 = L_3 = L_4 = \ldots\ldots$

$d_1 \neq d_2 \neq d_3 \neq d_4 \neq \ldots\ldots$

$$L = L_1\left[\frac{d^{2.638}}{d_1^{2.638} + d_2^{2.638} + d_3^{2.638}}\right]^{1.930} \quad \ldots\ldots\ldots [36]$$

Case 4. $L_1 \neq L_2 \neq L_3 \neq L_4 \neq \ldots\ldots$

$d_1 = d_2 = d_3 = d_4 = \ldots\ldots$

$$L = \left[\frac{d}{d_1}\right]^{4.830} \times \frac{1}{\left[\frac{1}{L_1^{0.546}} + \frac{1}{L_2^{0.546}} + \frac{1}{L_3^{0.546}} \ldots\right]^{1.930}} \quad \ldots [37]$$

Case 5. $L_1 \neq L_2 \neq L_3 \neq L_4 \neq \ldots\ldots$

$d_1 \neq d_2 \neq d_3 \neq d_4 \neq \ldots\ldots$

Use Equation [*B*]

Illustrative examples follow.

Example 1. What is the friction drop in a 6-in. pipe line one mile long if 1000 bbl. per hr. flow through this line? Viscosity of the oil is 200 Saybolt seconds universal, gravity 30 A.P.I.

$$\nu = 0.00000237 \times 200 - \frac{0.00194}{200} = 0.0004643$$

$$s.g. = \frac{141.5}{131.5 + 30} = 0.875$$

$$d \text{ (actual)} = 6.065 \text{ in.} = 0.505 \text{ ft.}$$

$$v = \frac{1000 \times 0.286}{(6.065)^2} = 7.8 \text{ ft. per sec.}$$

$$\frac{vd}{\nu} = \frac{7.8 \times 0.505}{0.0004643} = 8500$$

This indicates a turbulent flow and Equation [20] must be used

$$h_f = 4.79 \times 0.0004643^{0.170}\,\frac{1000^{1.830}}{6.065^{4.830}} = 67 \text{ ft. per } 1000 \text{ ft.}$$

and

$h_f = 5.28 \times 67 = 353$ ft. per mile

Next the question may arise what would be the friction drop for the same conditions using a combination as indicated in Fig. 5.

$L_1 = L_2 = 0.5$ mile

$d_1 = 6.065$ in. $= 0.505$ ft.

$d_2 = 7.981$ in. $= 0.665$ ft.

Using Equation [36]

$$L = 0.5\left[\frac{6.065^{2.638}}{6.065^{2.638} + 7.981^{2.638}}\right]^{1.830} = 0.5 \times 0.127$$

$L = 0.0635$ mile

therefore the total friction drop will be

$$h_f = \frac{353}{2} + 353 \times 0.0635 = 198.9 \text{ feet}$$

Checking up whether the turbulent flow still takes place we have from Equation [III]

$$v = \left[\frac{2g \times 22.4}{0.167 \times 0.0004643^{0.170}}\right]^{0.548}\left[\frac{(0.505)^{0.638}}{(2640)^{0.548}}\right]$$

v = 3.35 ft. per sec. in $^1/_2$ mile of 6-in. pipe

and

$$\frac{vd}{\nu} = \frac{3.35 \times 0.505}{0.0004643} = 3640$$

hence turbulent flow takes place and the use of Equation [36] is justified.

Example 2. What is the friction drop in a 6-in. line one mile long if 1000 bbl. per hr. of oil are moved at the viscosity of 1500 Saybolt seconds universal and 15 A.P.I. gravity?

$$\nu = 0.00000237 \times 1500 - \frac{0.00194}{1500} = 0.00356$$

$$s.g. = \frac{141.5}{131.5 + 15} = 0.965$$

d (actual) = 6.065 in. = 0.505 ft.

v = 7.8 ft. per sec.

$$\frac{vd}{\nu} = \frac{7.8 \times 0.505}{0.00356} = 1105$$

This indicates a streamline flow and Equation [12] must be used, hence

$$h_f = 41000\,\frac{1000 \times 0.00356}{6.065^4} = 108 \text{ ft. per 1000 ft.}$$

$$h_f = 5.28 \times 108 = 572 \text{ ft. per mile.}$$

Next calculate the friction drop if two parallel lines are used. One line is 6 in. and the second line is 8 in. in diameter. Both lines are one mile long.

From Equation [28]

$$L = l_1\,\frac{6.065^4}{6.065^4 + 7.981^4}$$

$$L = 0.25 \text{ mile}$$

$$h_f = 572 \times 0.25 = 143 \text{ ft.}$$

Accelerated Streamline Flow

When a pipe line is full, a certain amount of time must elapse before a steady flow is established.

In case of a turbulent flow the time necessary for a mass of fluid to reach velocity v when starting from zero under a constant head for a series flow may be expressed approximately by the equation, assuming the pipe rigid,

$$t = \frac{Lv'}{gh} \times \frac{1}{2} \ln_e \frac{v' + v}{v' - v} \quad \text{[IV]}$$

where t is the time in seconds corresponding to velocity v in feet per second; v' the final velocity of the steady flow, L the pipe length in feet, and h the head in feet.

To the author's knowledge no expression has been derived for a streamline flow, and an equation for determining the time required to establish a steady flow for a streamline flow will be presented. This problem is of special interest in connection with oil pipe lines where a streamline flow occurs when pumping oils of high viscosities.

Imagine a pipe line filled with oil. To pump a certain quantity of oil the head produced by the pump must be equal to the sum of the static, friction, and velocity heads, thus

h = static head + friction head + velocity head

Assume a streamline flow, that is, a flow for which vd/ν is less than 2000.

Considering the forces acting on the mass of fluid, we have a force due to pressure head awh, a retarding force due to friction head $\frac{64}{2gd^2} L v \nu a w$, and a retarding force due to velocity head $aw\frac{V^2}{2g}$.

Since velocity is not steady, the system is not balanced and the resultant force is measured by the acceleration imparted to the mass of liquid

$$m\frac{dv}{dt} = aL\frac{w}{g}\frac{dv}{dt}$$

and we may write, assuming that h is constant and the pipe rigid,

$$awh - \frac{64}{2g}\frac{L}{d^2} v\nu aw - aw\frac{v^2}{2g} = aw\frac{L}{g}\frac{dv}{dt} \quad \text{[38]}$$

dividing both sides of Equation [38] by $aw\frac{L}{g}$

$$\frac{gh}{L} - \frac{64}{2}\frac{\nu}{d^2} v - \frac{v^2}{2L} = \frac{dv}{dt} \quad \text{[39]}$$

to simplify, call

$$\frac{gh}{L} = C \quad \text{[40]}$$

$$-32\frac{\nu}{d^2} = B \quad \text{[41]}$$

$$-\frac{1}{2L} = A \quad \text{[42]}$$

and substituting in Equation [39]

$$C + Bv + Av^2 = \frac{dv}{dt} \quad \text{[43]}$$

Separating the variables

$$dt = \frac{dv}{C + Bv + Av^2}$$

Integrating both sides

$$t = \int_0^v \frac{dv}{C + Bv + Av^2}$$

Solving the integral on the right side of equation

$$t = \left[\frac{1}{\sqrt{B^2 - 4AC}} \log_e \frac{2Av + B - \sqrt{B^2 - 4AC}}{2Av + B + \sqrt{B^2 - 4AC}}\right]_0^v \quad \text{[44]}$$

If $t = 0$, $v = 0$ because there is no flow, and Equation [44] becomes

$$t = \frac{1}{\sqrt{B^2 - 4AC}} \log_e \left[\frac{2Av + B - \sqrt{B^2 - 4AC}}{2Av + B + \sqrt{B^2 - 4AC}}\right] - \frac{1}{\sqrt{B^2 - 4AC}} \log_e \frac{B - \sqrt{B^2 - 4AC}}{B + \sqrt{B^2 - 4AC}}$$

or

$$t = \frac{1}{\sqrt{B^2 - 4AC}} \left\{ \log_e \frac{2Av + B - \sqrt{B^2 - 4AC}}{2Av + B + \sqrt{B^2 - 4AC}} \times \frac{B + \sqrt{B^2 - 4AC}}{B - \sqrt{B^2 - 4AC}} \right\} \quad \ldots\ldots [45]$$

If the flow becomes steady, that is, when $v = v'$, Equation [43] becomes

$$C + Bv' + Av'^2 = 0$$

and solving for v'

$$v' = \frac{-B \pm \sqrt{B^2 - 4AC}}{2A}$$

or

$$2Av' + B = \pm \sqrt{B^2 - 4AC} \quad \ldots\ldots [46]$$

Since A and B are negative and v' is positive, the left side of Equation [46] is negative and consequently minus sign should be used for the right side of the equation

$$2Av' + B = -\sqrt{B^2 - 4AC} \quad \ldots\ldots [47]$$

Substituting in Equation [45]

$$t = \frac{1}{-2Av' - B} \log_e \frac{2Av + B + 2Av' + B}{2Av + B - 2Av' - B} \times \frac{B - 2Av' - B}{B + 2Av' + B}$$

or

$$t = \frac{1}{-2Av' - B} \log_e \frac{2A(v + v') + 2B}{2A(v - v')} \times \frac{-Av'}{B + Av'}$$

and finally

$$t = \frac{1}{-2Av' - B} \log_e \frac{A(v + v') + B}{A(v - v')} \times \frac{-Av'}{B + Av'} \quad \ldots\ldots [48]$$

When the flow is steady $v = v'$ and Equation [48] becomes

$$t = \frac{1}{-2Av' - B} \log_e \frac{2Av' + B}{A(O)} \times \frac{-Av'}{B + Av'}$$

but $\log_e \frac{K}{0} = \infty$ and it will take an infinite time for the mass of liquid to acquire the final velocity v'.

In practice the time necessary for the mass to acquire a velocity somewhat smaller than v' is of interest and a graph showing the relation between v and t must be plotted. This graph will indicate the value of t at which the flow becomes practically steady.

An example illustrative of this equation follows.

Required to pump 500 bbl. of oil per hour through a 6-in. line one mile long. The viscosity of the oil at the pumping temperature is 1000 Saybolt seconds universal, 17.5 A.P.I. gravity. Determine the time required to obtain a steady flow, assuming that the head created by the pump is constant and the pipe rigid.

First determine the ratio vd/ν.

$d = 6.065$ in. $= 0.505$ ft.

$$v = \text{bbl. per hr.} \frac{0.286}{d^2} = 500 \times \frac{0.286}{6.065^2} = 3.9 \text{ ft. per sec.}$$

$$\nu = 0.00000237T - \frac{0.00194}{T} = 0.00237$$

and

$$\frac{vd}{\nu} = \frac{3.9 \times 0.505}{0.00237} = 831$$

This indicates that a streamline flow takes place and Equation [48] should be used.

From Equations [41] and [42]

$$A = -\frac{1}{2L} = -\frac{1}{2 \times 5280} = -\frac{1}{10560}$$

$$B = -32\frac{\nu}{d^2} = -32\frac{0.00237}{0.505^2} = -0.297$$

Substituting in Equation [48]

$$t = \frac{1}{\frac{2}{10560} \times 3.9 + 0.297} \ln_e \frac{-\frac{1}{10560}(v + 3.9) - 0.297}{-\frac{1}{10560}(v - 3.9)} \times \frac{\frac{1}{10560} \times 3.9}{-0.297 - \frac{3.9}{10560}}$$

$$t = 3.36 \ln_e \frac{v + 3133.9}{3.9 - v} \times 0.001245$$

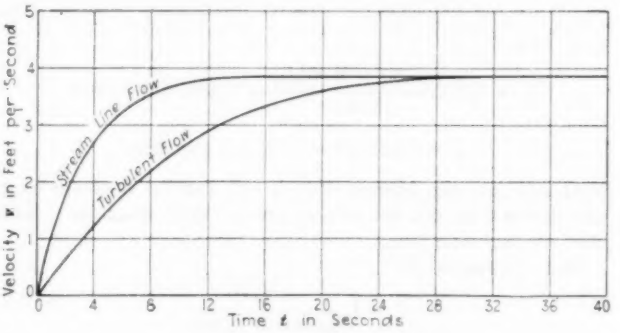

FIG. 6 TIME-VELOCITY CURVE

Substituting the different values of v and tabulating we have

v	t
0	0
1.0	1.0
2.0	2.41
3.0	4.95
3.5	7.65
3.80	12.3
3.85	14.7
3.90	$\sim$

These values are plotted (Fig. 6) and it is evident that after 13 sec. practically a steady flow is established.

If water instead of oil be pumped at the same rate (500 bbl. per hr.) through the same line,

$d = 0.505$ ft.

$v = 3.9$ ft. per sec.

$$\nu = 0.00000237 \times 30.99 - \frac{0.00194}{30.99} = 0.00001077$$

and

$$\frac{vd}{\nu} = \frac{3.9 \times 0.505}{0.00001077} = 183000$$

which indicates a turbulent flow and Equation [IV] must be used. From Equation [20]

$$h_f = 4.79 \times 0.00001077^{0.170} \frac{500^{1.830}}{6.065^{4.830}}$$

h_f = 9.8 ft. per 1000 ft.
h_f = 51.7 ft. per mile

Substituting in Equation [IV]

$$t = \frac{5280 \times 3.9}{32.2 \times 51.7} \times \frac{1}{2} \log_e \frac{3.9 + v}{3.9 - v}$$

Substituting the different values of v and tabulating the results we have,

v	t
0	0
1.0	3.25
2.0	7.02
3.0	12.65
3.5	18.1
3.80	27.0
3.85	31.3
3.90	$\sim$

These values of v and t are plotted in Fig. 6.

Discussion

J. M. Spitzglass.[2] In following the dimensional analysis of the flow formulas as given in the paper, I was in agreement with the derivation of Equations [2], [3], and [4] until I reached the substitution of h_f for p. I applied the dimensional formula to the expression $p = h_f \rho \cdot \frac{M}{LT^2}$ is not equal to $L \frac{M}{L^3}$. The correct expression should be

$$p = hg\rho \cdot \frac{M}{LT^2} = L \frac{L}{T^2} \cdot \frac{M}{L^3} = \frac{M}{LT^2}$$

This omission corrected itself later by calling $K = \frac{K_0}{2g}$; still the expression $p = h_f \rho$ as it stands is not dimensionally correct. I would suggest that the author insert the $2g$ into that expression, which would make the change from K to K_0 much clearer.

The derivation of Equation [5] requires additional explanation. It should be stated that the division of the factors is made arbitrarily to conform with the time-honored formula $h_f = 4f \frac{L}{d} \frac{V^2}{2g}$. The second factor is the dimensionless part that stands for f, the coefficient of friction. The correlation with Poiseuille's experiments is of interest. It may be stated that Equation [I] for streamline flow is more fundamental than Equation [6], even though the latter is more general.

Grant K. Palsgrove.[3] The author has presented a group of general formulas for frictional resistance offered to flow in straight, circular pipes of relatively smooth surface in a manner that makes the solution of problems of this nature comparatively simple. The writer, however, wishes to call the attention of the author to many inconsistencies, lack of proper acknowledgment, and errors in this paper.

In the first part, pertaining to the resistance offered to flow, all of the equations and derivations (with the possible exception of the form of the factor K as found from the author's Fig. 4) are to be found in the well-known book on "Hydraulics and Its Application," by A. H. Gibson (1921).

Why present Equation [1] for streamline flow and no corresponding equation for sinuous flow? We have such equations deduced by Williams, Hubbell, and Fenkell and also by Bazin and Darcy, all of which give close agreement with practice (again see Gibson).

Equation [5] is Osborne Reynolds' equation with a modified constant, Reynolds giving the equation as follows:

$$h_f = \frac{LB^n \left(\frac{\mu}{\rho}\right)^{2-n} V^n}{A\, d^{3-n}},$$

in which $\frac{B^n}{A}$ corresponds to $\frac{K_0}{2g}$ in the author's equation.

Equation [6] should be given as

$$h_f = \frac{L}{d} \frac{V^2}{2g} \phi \left(\frac{vd}{\nu}\right)^{n-2}$$

with a statement to the effect that Poiseuille found that for all surfaces with streamline flow $\phi = 64$ and $n = 1$. This is then Equation [I] given by the author. Reynolds found from various experiments with smooth pipes and sinuous or turbulent flow that $n = 1.83$ as an average, and with $\phi = 0.167$ gives the author's Equation [II].

In outlining the cases likely to be found in practice, the author has applied the law of variation to Equations [I] and [II] very well indeed.

With reference to the second part of the paper, on Accelerated Flow, the writer again wishes to call the author's attention to the work of Professor Gibson wherein the subject of accelerated flow has been covered in detail without regard to the type of flow (streamline or sinuous). Gibson derives a general equation which is rigorously true for an incompressible fluid in a rigid pipe and is of the form:

$$t = \frac{K}{2V'} \log_e \frac{v' + v}{v' - v}$$

in which $k = \frac{2L}{1 + \frac{64}{\left(\frac{vd}{\nu}\right)} \frac{l}{d}}$ for streamline flow

and $k = \frac{2L}{1 + \frac{0.167}{\left(\frac{vd}{\nu}\right)^{0.17}} \left(\frac{l}{d}\right)}$ for turbulent flow.

Applying the foregoing equation to the author's examples gives:

For oil (where streamline flow was indicated), at an assumed velocity $v' = 3$ ft. per sec.

$$t = \frac{2 \times 5280}{\left[1 + \frac{64}{831}\left(\frac{5280}{0.505}\right)\right]} \times \frac{1}{2 \times 3.9} \log_e \frac{3.9 + 3}{3.9 - 3} = 3.43 \text{ sec.}$$

and for $v' = 3.85$ ft. per sec., $t = 8.5$, etc. This shows a curve somewhat above the one indicated by the author for streamline flow in Fig. 6.

For water (where turbulent flow was indicated), at an assumed velocity $v' = 3$ ft. per sec.

[2] Mechanical Engineer and Vice President, Republic Flow Meters Company, Chicago, Ill. Mem. A.S.M.E.

[3] Professor of Hydraulic Engineering, Rensselaer Polytechnic Institute, Troy, N. Y. Mem. A.S.M.E.

$$t = \frac{2 \times 5280}{\left[1 + \frac{0.167}{(183000)^{0.17}}\left(\frac{5280}{0.505}\right)\right]} \times \frac{1}{2 \times 3.9} \log_e \frac{3.9 + 3}{3.9 - 3}$$

$$= 12.3 \text{ sec.}$$

and for $v' = 3.85$ ft. per sec., $t = 30.5$, etc. This shows a curve which is below that for streamline flow as indicated by the author on Fig. 6, and very far different from the author's curve for turbulent flow. Upon checking Equation [IV] with the foregoing one given by Gibson, the two are identical. Further checking shows that the author not only has an error in decimal point for "t" values, but also has errors in some of the figures, which when corrected agree with the values obtained in the foregoing.

The writer would like to question the general use of Equation [48], which is deduced on the basis of Equation [47], and therefore only holds for the case of zero acceleration or $v' = v$ and for no other case. Hence the difference between the author's values of t at different velocities assumed and those of Gibson for streamline flow. Gibson's equation is based strictly on the application of the well-known Bernoulli theorem.

Author's Closure

Mr. Spitzglass correctly pointed out that to make the derivation of the Equation [5] correct the expression for the pressure should be

$$p = h_f \delta g$$

This has been changed accordingly.

In reference to Professor Palsgrove's criticism on the first part of the article, the writer wishes to state that Professor Palsgrove overlooked that due credit was given to Professors Reynolds and Poiseuille.

So far as Equation [5] is concerned, it is nothing else but the well-known exponential formula. The derivation of this equation was reviewed for the better understanding of the latter part of the article.

Having looked carefully through Professor Gibson's book on "Hydraulics" the author failed to find any attempt to solve the problem of accelerated streamline flow and did not find any equation presented in the final form as used by the author in his article. And for this reason, with all due respect to the genius of Professor Gibson, the author does not see where he could refer to Professor Gibson's "Hydraulics."

Professor Palsgrove's statement that the Equation [6] should be given in form

$$h_f = \frac{L}{d} \frac{V^2}{2_g} \phi \left(\frac{vd}{\nu}\right)^{n-2}$$

is incorrect, since ϕ is not a coefficient, but is a mathematical symbol meaning a function. Consequently, the exponents and coefficients should be omitted as long as symbol ϕ is used. (See introduction to "Differential and Integral Calculus," page 4, by Osgood.)

In reference to Professor Palsgrove's criticism on the third part of the article, the Equation [IV] was presented in its final form only for the sake of comparison with that derived by the author for the streamline flow and was in no place claimed to be original. That the final results obtained by means of this equation check up with that of Professor Gibson's equation is quite natural, and undoubtedly it will check with all similar equations presented in other treatises and text books, provided that they are correct, although they might be stated in different form.

The author does claim, as stated in the article, that to his knowledge no expression has been derived for determining the time required to establish a steady flow for a streamline flow.

To present the derivation of the Equation [48], show its application, and compare the results with those obtained for turbulent flow by means of Equation [IV] was the author's aim in the third part of the article.

Concerning the deduction of Equation [48] on the basis of Equation [47], it is correct and holds theoretically for any value of acceleration.

The substitution of one set of constants A, B, and C by another constant v' is nothing else but simple algebra and does not change the physical meaning of the equation.

The author acknowledges his appreciation for pointing out the numerical errors, which are rectified.

Experimental Study of Loss of Head in a Closed Pipe Carrying Clay Slurry[1]

By CHARLES HANOCQ,[2] LIEGE, BELGIUM

Taking as a basis for his calculations the formulas presented in a previous paper by an American investigator on the loss of head in a closed pipe carrying clear fluids, the author, a Belgian engineer, seeks to apply them to a fluid carrying a heavy proportion of solid materials. The author takes the conclusions in the original paper, which he assumes seem at first sight somewhat contradictory, and shows that no anomalies exist, and further brings out some precise deductions on the loss of head in a pipe carrying muddy water.

AN INTENSELY interesting study published in the June, 1927, number of *Mechanical Engineering* allows us, in using the method that we have proposed for the calculation of loss of head,[3] to examine in what measure these formulas for homogeneous fluids can be applied to a fluid holding in suspension a large proportion of solid materials. Having had occasion to conduct the experiments on a sufficiently large scale with a view to determine the losses of head in a pipe 4 in. in diameter supplied by a centrifugal pump, pumping a muddy water more or less charged, W. B. Gregory, professor at Tulane University in America,[4] has furnished some very complete experimental information and has brought forth certain important conclusions—although at first sight they apparently are contradictory.

In following the analysis of results by means of our method, we have been able to dispel these anomalies and to bring out some precise deductions concerning the calculation of the loss of head in the particular case of muddy waters.

The experiments have been made on a cast-iron pipe measuring in length 112.5 meters, with the amount by weight of the material in suspension varying from 0 to 35 per cent, the specific weight being respectively from

1000 at 0.0%
1130 at 18.6%
1175 at 23.4%
1225 at 29.05%
1255 at 32.5%
1285 at 35.3%

The experiments made on the new pipe with clear water have shown that the losses of head were slightly greater than those which would be calculated by means of the formula proposed by us.[5]

The unforeseen result, after this pipe had been placed in service with the muddy water, was that the losses of head were found reduced to those which are observed in a smooth pipe. It is thus that the experiments made with turbid water and of a density practically equal to unity have given values which agree exactly with those deduced from our formula

$$10^5\beta = \frac{271.8}{\sqrt[3]{\alpha}} + 3.4$$

applicable to smooth pipes.

These results can be explained by admitting that the deposit on the walls of the pipe of a coating of the materials held in suspension has had the effect of transforming the rough surface of the pipe to a practically smooth surface.

We have already been led to make an analogous observation in the case of pumping petroleum oils; the formula applicable to iron pipes must be replaced by those for smooth pipes when the fluid used is relatively very viscous and adheres perfectly to the walls.[6]

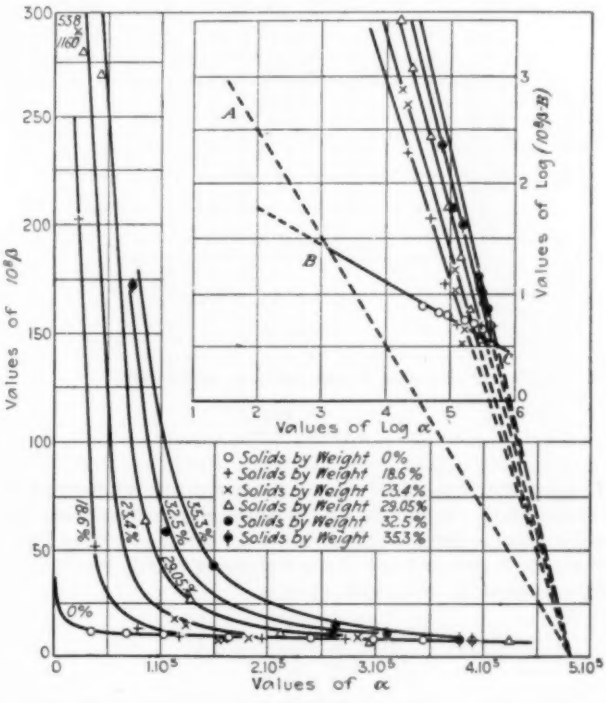

FIG. 1

Another unforeseen result is that for a certain value of the Reynolds coefficient varying with the amount of matter in suspension, the coefficient $10^5\beta$ which fixes the loss of head is found to be strictly equal to that observed in a pipe with smooth walls through which clear water is forced.

In other words, beginning with a certain critical value of α_c, turbulent flow is established and the loss of head is no longer influenced, beginning from this moment, by the presence of the suspended matter.

This conclusion does not seem likely to be general; we cannot hold it to be true, for the lack of verification of the most general conditions, of materials in suspension heavily charged and for materials in excess of 35 per cent, in round numbers.

It is known that the loss of head in meters of fluid flowing is given by the formula

$$h = 10^4\beta \frac{w^2}{d} L$$

To use this formula we transformed the differences of pressure indicated by the author in height of meters of pure water to heights with the density of the fluid used in the experiment.

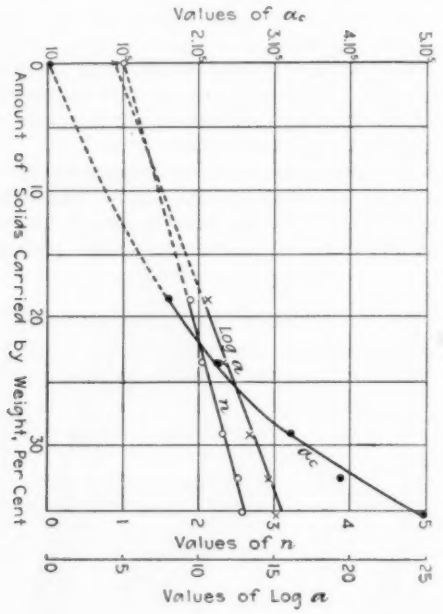

FIG. 2

In carrying as abscissas α furnished by the formula

$$\alpha = \frac{10\delta w d}{\mu}$$

(μ being the viscosity of the clear water at the temperature indicated and δ the specific weight of the mixture) we have been able to deduce from the experiments the curves of $10^4\beta$ of Fig. 1; the curve corresponding to 0 per cent, being exactly that deduced by our formulas for smooth pipes, is

$$10^4\beta = \frac{271.8}{\sqrt[3]{\alpha}} + 3.4$$

From these curves we have been able to deduce the position of the asymptotes, 3.4 to the common curve, then to calculate

$$\log (10^4\beta - 3.4)$$

In carrying these values as ordinates and the log α as abscissas we have obtained the curve BC of Fig. 1, which shows that, beginning with a certain value of α_c, variable with the amount of material carried, the law changes completely.

Admitting that at the attainment of this value α_c the appreciable formula is that of viscous flow ("régime laminaire")

$$10^4\beta = \frac{a}{\alpha^n}$$

we have calculated log $10^4\beta$ and carried the results as ordinates.

As the dotted curve AB represents the law of viscous flow for clear water, it may be admitted that as the weight of material carried diminishes, the inclination of the line representing the law of variation of log $10^4\beta$ diminished as it approaches the dotted line. We propose for lack of something better and in recognition that the results given are insufficient to obtain in a relatively sure method the direction of the curve, the law of variation of α_c as a function of the weight of materials in suspension represented by the curve of Fig. 2.

It follows from this for the lower values of α_c that the formula to apply is that of viscous flow, and must be

$$10^4\beta = \frac{a}{\alpha^n}$$

the coefficients a and n being given by the curves of Fig. 2. (a is given by log a.) It is seen that for materials carried from 18 per cent to 30 per cent the least value of n is equal to 2, then for clear water $n = 1$; $10^4\beta = \frac{a}{\alpha}$. This explains the direction of curves of the loss of head given by the author, which shows that these are independent of the velocity below a certain value of α, varying with the amount of solid material carried.

In fact, if in the formula for the loss of head $h = 10^4\beta\frac{w^2}{d}$ we introduce the value found $10^4\beta = \frac{a}{\alpha^n}$ applicable below the critical velocity, then we will have

$$h = 10^{-4} \frac{a}{\left(\frac{10\delta d}{\mu}\right)^n w^n} \frac{w^2}{d}$$

which will furnish for $n = 2$ a value of $h = a$ constant, whatever

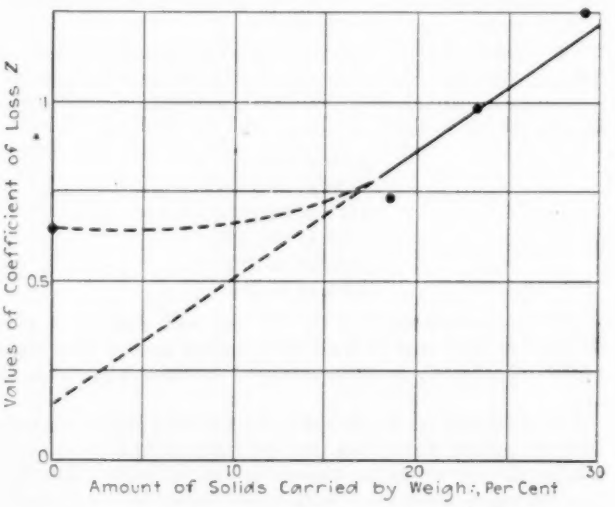

FIG. 3

is the velocity, from the moment when the critical velocity is not exceeded. This conclusion is only truly evident for the amount of material between 18 and 30 per cent, for which the average value of n stays equal to $n = 2$.

This manner of considering the total of the experimental results leads us to suppose that the presence of solid particles in suspension tends to maintain longer the viscous flow ("régime laminaire"), but that the particles in increasing the friction surfaces cause an increase in unusual proportions of the resistance to flow and consequently the loss of head. As soon as the turbulent flow is established, on the contrary the loss of head is maintained

constantly equal to that which would be observed in a smooth pipe through which runs a fluid having the viscosity of water and the same average density as the mixture.

These results deduced with our method, in terms of Reynolds' coefficient, are extremely curious because they indicate that the phenomenon of the flow of a fluid holding in suspension some particles does not depart essentially from the usual phenomenon of flow of a homogeneous fluid in the region of viscous flow at least.

This conclusion is nevertheless only true for straight pipes. For the curved pipes the results furnished by the experiments of Mr. Gregory show that the losses, if one compares them with those through which the clear water flows under the same conditions, increase rapidly with the weight of material in suspension. This difference in the assumed conclusions suggests that the deviation of the filaments has an effect to provoke a separation of the particles of the fluid themselves and to lead to a concentration of solid particles at the exterior walls. It is no longer possible from this moment to apply relatively simple laws to translate the results of the experiments.

Fig. 3 gives the value of the coefficient Z of the classic formula of supplementary losses due to an elbow

$$h = Z \frac{w^2}{2g}$$

The curve traced as a function of the per cent of solids by weight shows that the coefficient Z is proportional to the per cent of solids beginning at 18 per cent. For the observed loss with turbid water, carrying only a small quantity of solids, the author has obtained the figure 0.64 indicated on the axis of ordinates. This very high figure explains with difficulty as the one generally indicated in the formulas for a curve at 90 deg., and a corresponding value $\frac{d}{r}$ is equal to 0.15. If this last figure should be considered as the true figure for clean water in a clean pipe, we must conclude that the coefficient Z increases proportionally with the per cent solids by weight; the absence of points between 0 and 18 per cent does not permit us to venture an opinion in this regard.

This conclusion, which concerns the intersection of losses with the per cent of solids by weight, is confirmed by the figures observed for the manometric height furnished by the pump during the tests on the pipes.

In evaluating the heights observed in meters of fluid having the average density of the liquid pumped, we have been able to calculate the manometric height as a function of the discharge, the peripheral velocity remaining constant. The curve 1 (Fig. 4) refers to clear water, curve 2 to 18.6 per cent, curve 3 to 23.4 per cent, curve 4 to 29.05 per cent solids by weight.

For the curves 2, 3, and 4 the points observed group themselves relatively well on the mean curve; furthermore these curves indicate a loss of head rapidly increasing with solids carried in the passages of the impeller and of the volute.

Finally, if the law stated apropos of straight pipes remains true for curved passages, we must observe, at least in the region of the turbulent flow, a unique curve for all the per cents of solids carried up to 29 per cent.

For the per cents of solids carried below 29 per cent, the points observed are absolutely scattered, and it will be impossible to rely upon them for continuous curves; this holds true that the more and more complete separation of solid particles at the time of the passage on the blades of the wheel makes the local densities very much higher than the mean densities and that all the deductions made to define that which one expects regarding manometric heights and least discharge cease to be significant from this moment.

Conclusions

In admitting, for lack of something better, the diagram of 2 for the values of α_c, a, and n, one sees that the calculation of the loss of head for muddy water containing up to 35 per cent of material in suspension may be made in the following manner:

If α is greater than α_c, we have in meters of fluid pumped

$$h = 10^4 \beta \frac{w^2}{d}$$

with

$$10^3\beta = \frac{271.8}{\sqrt[3]{\alpha}} + 3.4$$

the coefficient α being calculated for the density equal to that of

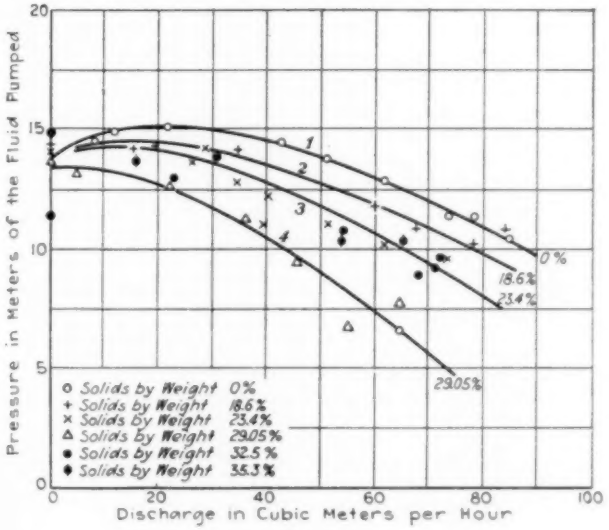

Fig. 4

the fluid pumped, and for viscosity equal to clear water at the temperature given.

If α is less than α_c, we have still

$$h = 10^4 \beta \frac{w^2}{d}$$

but with

$$10^3\beta = \frac{a}{\alpha^n}$$

the coefficient α being calculated as in the first case and the coefficients a and n being furnished by the diagrams of Fig. 2.

It is possible to use the formulas giving directly the values of $10^3\beta$ in noting that all the lines representing the viscous flow for different percentages for solids carried converge toward the same point (see Fig. 1).

This point being characterized by

$$\log \alpha = 6.88, \log 10^3\beta = -2.366$$

the relation

$$\log 10^3\beta = \log a - n \log \alpha$$

furnishes

$$\log a = 6.88\, n - 2.366$$

it follows that

$$\log 10^8\beta = n(6.88 - \log \alpha) - 2.366$$

The coefficient n being furnished as a function of the weight of solids x per cent of the materials in suspension, by the linear law,

$$n = 0.045\, x + 1$$

it will be possible to deduce a relation between $10^8\beta$ and α which will fix directly the value of β as a function of x and of α.

$$\log 10^8\beta = 0.31x + 4514 - (0.045x + 1) \log \alpha$$

Grouped under this form, the results of these very complete tests made by Mr. Gregory present a general interest which will escape none, being given in such a way that they may be considered, in my opinion, as valuable in all their applications, whatever be the nature of the solid particles entering the problem, at least if they have small enough dimensions to remain in suspension even at a low velocity.

Permissible Suction Head of High-Speed Propeller Turbines

By ARNOLD PFAU,[1] MILWAUKEE, WIS.

The paper discusses the general phenomena of pitting and cites the underlying causes. It explains the necessity for special caution in the selection of the setting of a high-speed propeller turbine. To fully realize these causes a new explanation is given of the flow conditions in a high-speed propeller, and it shows that these conditions add an item to the suction head which does not enter into the problem with reaction or action turbines. Particularly this paper emphasizes the wide variation in the characteristics of turbine runners that are termed the "propeller type" and directs attention to the difficulty that may be encountered from generalization based on the use of a single mathematical equation or expression.

IT IS known from experimental researches[2] that cavitation, and in some cases also vibration, sets in when the negative pressure becomes so low that the vapor point of the operating water is reached. At this point the water begins to "boil," and it forms air or vapor pockets which when adjacent to the surface of a blade cause the water to separate or to "cut loose." When these pockets again collapse, the water is thrown against the blade surface with a tremendous force (more than 7000 tons per square inch), so that a mechanical destruction of the material is brought about, manifested in what we term "erosion." The intense and exceedingly rapid pressure changes of an adiabatic nature also may be responsible for the possible existence of chemical processes which produce gases (oxygen, carbon dioxide, ammonia) and which attack the metal, resulting in what we term "corrosion," all of which brings about a destruction of the blade and reduces the efficiency and the life of the runners.

These negative pressures are a function of three principal factors:

1 Suction height H_s (vertical distance from runner to tail water level)
2 Regain in draft tube, $h_r = e\ (V_2^2/2g - V_3^2/2g)$, as explained farther on
3 Barometric pressure B in feet of water column (dependent on the elevation above sea level, 33.8 ft. at sea level).

The vapor point of the water is reached at a pressure equivalent to about $^1/_3$ to $^2/_3$ ft. of absolute water column at normal temperature.

Neglecting this vapor pressure, we have

$$B - H_s - e \cdot \left(\frac{V_2^2}{2g} - \frac{V_3^2}{2g}\right) \geqq 0$$

e represents the efficiency of regain (or deceleration) in the draft tube
V_2 is the absolute velocity of water below the runner (at the top of the draft tube)
V_3 is the exit velocity of water at the end of the draft tube.

Since $K_{v2} = V_2/\sqrt{2gh}$, we have $\dfrac{V_2^2}{2g} = K_{v2}^2 \cdot H$

also, $K_{v3}^2 \cdot H = \dfrac{V_3^2}{2g}$

and we can write

$$H_s \leqq B - e \cdot h(K_{v2}^2 - K_{v3}^2)$$

as the theoretical limit of suction height. It is evident that higher and higher velocities V_2 require a smaller and smaller suction height H_s. (High exit velocities V_3 and low regain or draft tube efficiencies e permit of a greater suction height H_s.) With the introduction of the modern, more efficient forms of draft tubes, the danger limit of cavitation is approached sooner than was the case with older, less efficient designs. The increase of specific speeds has increased the coefficient of discharge K_{v2}, which again brings the danger line closer. With runners of moderate specific speed K_{v2} was about 0.25 and with draft tubes of only 40 per cent efficiency and an exit velocity K_{v3} of, say, $0.1 \cdot \sqrt{2gh}$ we obtain for the setting at sea level ($B = 33.8$ ft.)

$$H_s \leqq 33.8 - 0.4 \cdot H \cdot (0.25^2 - 0.1^2) \text{ or } \leqq 33.8 - 0.021 \cdot H$$

$$\text{for } H = 100 \text{ ft.} \qquad H_s \leqq 31.7 \text{ ft.}$$

Assume now a higher specific speed with $K_{v2} = 0.45$, a draft tube efficiency of 75 per cent, and an exit velocity equivalent to $K_{v3} = 0.05$, we obtain:

$$H_s \leqq 33.8 - 0.75 \cdot H(0.45^2 - 0.05^2) \text{ or } \leqq 33.8 - 0.15 \cdot H$$

$$\text{for } H = 100 \text{ ft.} \qquad H_s \leqq 18.8 \text{ ft.}$$

The foregoing values of H_s are theoretical. A liberal margin of safety must be allowed if the water enters the draft tube, not in streamlines parallel to the axis, but discharges with a forward or backward whirl which produces centrifugal forces resulting in an additional suction effect at the inner portions of the top of the draft tube. (If the turbine is to operate at a high elevation above sea level, say, 6000 ft., B is correspondingly less, thereby reducing the allowable suction head H_s still further.)

Propeller Turbine

Literature on the subject classes the propeller turbine with the so-called "suction jet" or under-pressure turbines. This is incorrect as not every propeller turbine is an under-pressure turbine. On the other hand, it seems that under-pressure turbines can be built successfully only with runners of the propeller shape. From a purely theoretical standpoint the modern type of turbines can be placed in three typical classes:

1 Over-pressure (or reaction) turbine, in which the pressure due to the available head H is only partly transformed into velocity, so that an actual over-pressure ($p_r = a \cdot \dfrac{c_r^2}{2g} > 0$) exists between guide case and runner. This pressure, called the reaction pressure, produces the acceleration of the relative water velocity in the runner passages ($W_2^2 - W_1^2 = C_r^2 > 0$), thus $W_2 > W_1$, and a peripheral speed, which increases with the increase of p_r and which increases the specific speed n_s.

2 Action (or impulse) turbines, in which the pressure due to available head H is completely transformed into velocity so that the over-pressure p_r between guide case and runner (or

[1] Consulting Engineer, Hydraulic Department, Allis-Chalmers Mfg. Co. Mem. A.S.M.E.

[2] "Hydraulische Probleme," pp. 14–79, *V.D.I.*, Berlin, 1926.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

nozzle and buckets of an impulse wheel) is zero, i.e., atmospheric pressure. Here no acceleration of the relative water velocities takes place ($W_2^2 - W_1^2 = C_r^2 = 0$); thus ($W_2 = W_1$), except that due to centrifugal action. The absence of an over-pressure p_r is here responsible for the fact that the peripheral speed $K_u = \frac{D \cdot \pi \cdot n}{60\sqrt{2gh}}$ is fixed within much closer limits (0.42 to 0.48) than is the case with a reaction turbine where the values of K_u vary between 0.55 and 1.0 or more, depending upon the respective specific speed.

3 Under-pressure (or suction jet, or as commonly but not correctly called the propeller turbine), in which not only all of the pressure due to the available head H is transformed into velocity, but in which at a certain cross-section a velocity exceeding the spouting velocity $(\sqrt{2gh})$ is reached and where even an under-pressure exists, with subsequent retardation of the relative water velocities. ($W_2^2 - W_1^2 = C_r^2 < 0$, thus $W_2 < W_1$.)

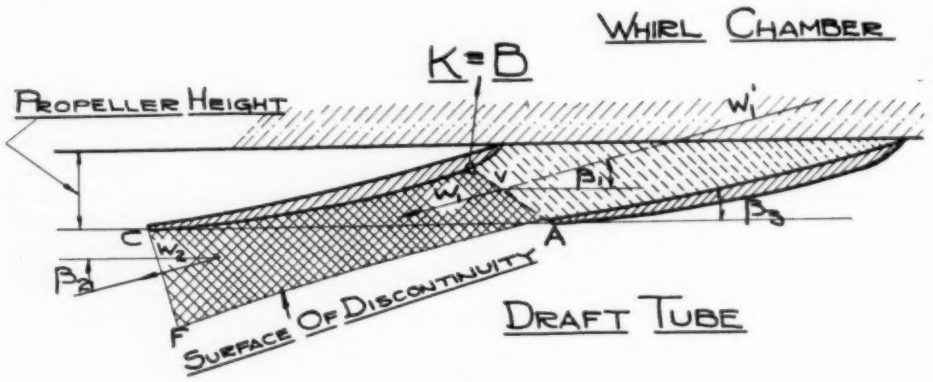

FIG. 1

In order to explain this process of the flow of water it is necessary to divide an under-pressure turbine into three stages, as illustrated in Figs. 2 and 3:

1 The guide case, where only a small portion of the pressure due to the available head H is transformed into velocity, and where the water is given an initial whirl in accordance with the arrangement of guide-vane angles or of passages between same ($V^2 = C_u^2 - C_r^2$; $C_r \gg 0$; $V \ll C_u$).

2 A whirl chamber, or free passage between the guide case and the runner (propeller). Here the water is changed from an essentially radial inward flow to an axial flow. The absolute velocity of water v is greatly increased v_1 and the whirl is somewhat modified, as will be explained in the discussion of velocity diagrams further on (α changes to α').

3 The inlet portion of the runner, extending from the entrance plane of the runner to a section in which the displacement area F by the projected runner vanes is a maximum, i.e., where the absolute water velocity is a maximum (V_{c1}).

$$V_{c1} = \frac{Q}{[(D_a^2 - D_i^2) \cdot \pi/4 - F] \cdot \sqrt{2gh}}$$

in which

D_a = runner diameter in feet at the plane in question
D_i = hub diameter in feet at the plane in question
F = projected displacement of vanes in square feet.

The corresponding maximum relative velocity W_1 is found in the cross-section A to K (Fig. 1) extending from point A (the discharge edge of the runner vane) to a point K located on the rear surface of the preceding runner vane. This is the same point as indicated and designated K, Fig. 1, *Swiss Bauzeitung*, vol. 91, no. 11, March 17, 1928, by Chief Engineer J. A. Ackeret, Zurich, and is in accord with observations made by the Aerodynamic Laboratory, Goettingen, Germany. (See Oldenbourg, Muenchen, 1927, page 132.) It is the point where the pressure p_r is a minimum, even negative.

The author's suggestion, made some nine years ago, seems therefore reasonable, i.e., to divide the under-pressure runner in two sections—the upper part ending with AK and performing similar duty to that of the rotating guide case of the so-called transformer turbine proposed about 1900 by Prof. Dr. Franz Prasil, at the Polytechnic of Zurich, Switzerland, and the lower part comprised by the triangles CKA. With this picture before us, it at once becomes evident that sections AK constitute what may be termed the "throat areas" of the runner, at which both the relative velocity W_1 and the corresponding absolute velocity V_1 are a maximum. That this absolute velocity may exceed even the value of the spouting velocity $\sqrt{2gh}$ can be explained as follows:

From the cross-sections AK, limited sidewise by the walls of the runner hub and of the stationary discharge ring (Fig. 2), the water passes downward through what I wish to term "hypothetical channels." These are formed by the rear surface CK of a blade, by the walls of runner hub and discharge ring, and by a surface of discontinuity AF which adjusts itself according to the speed and quantity of water and the angle β_3 at the throat A, which is not the outlet of the runner but the outlet of the rotating case, or accelerator.

The existence of a surface of discontinuity AF undoubtedly accounts for the great flexibility of efficiency as a function of the speed.

From the foregoing it at once becomes clear, and this is also proved by tests, that the angle β_3 can be reduced to 0, or even be negative, without seriously affecting or entirely negating the surface of discontinuity. Angles β_3 of zero value or less, if considered as relative runner discharge angles according to the old theory, would render the use of the conventional velocity diagrams impossible.

These hypothetical channels are individual diffusers in which the relative velocity W_1 at the entrance is gradually reduced to W_2 at the rear end C of the runner blade. It is at point C, therefore, where we find the actual relative discharge angle β_2 for use in our velocity diagram.

From $W_2^2 - W_1^2 = C_r \leqq 0$, the under-pressure $p_r = a \cdot C_r \leqq 0$ is at once explained, and also the fact that a "hydrodynamic suction" is produced in the under-pressure turbine, which is responsible for the high discharge capacity of this type of turbine and for the high rotating speed. To the regain in the draft tube

$$e \cdot H \cdot (K_{v2}^2 - K_{v3}^2)$$

we must therefore add the hydrodynamic regain

$$H \cdot (K_{v1}^2 - K_{v2}^2)$$

so that we obtain for the under-pressure turbine

$$H_s \leqq B - H \cdot [(K_{v1}^2 - K_{v2}^2) - e \cdot (K_{v2}^2 - K_{v3}^2)]$$

or as an approximation, by assuming that the efficiency of the hydrodynamic regain equals about that of the draft tube, we obtain

$$H_s \leqq B - e \cdot (K_{r1}^2 - K_{r3}^2);$$

for high specific speed under pressure turbines the value of K_{r1} exceeds unity. Values as high as 1.1 have been tested for $n_s > 200$. Applying this value again in the previous example, we have

$$\begin{aligned} K_{r1} &= 1.1 \\ V_3 &= 0.05 \\ e &= 0.75 \\ H_s &\leqq B - 0.75 \cdot H(1.1^2 - 0.05^2) \\ \text{or} \quad &\leqq B - 0.9 \cdot H \\ \text{for} \quad H &= 100 \text{ ft.} \\ H_s &= 33.8 - 90 = -56.2 \text{ ft.} \end{aligned}$$

From this it follows that for a 100-ft. head such an under-pressure runner would have to be submerged below the tail water 56.2 ft. in order to avoid danger of cavitation.

With the introduction of the hypothetical channel and the consequent modifications of the velocity diagrams, the process of the under-pressure turbine has been found to be identical with that and with the diagrams discussed in the literature in 1914 by Prof. Dr. Hans Baudisch of Vienna under the appropriate title "Saugstrahl Turbinen-Theorie" (Theory of the suction jet for under-pressure turbines).[3] Unfortunately the design of the runner then proposed by Professor Baudisch failed to give the desired results, because his runner was designed with four-wall channels in which it was intended to force a deceleration of the relative flow of water. The channels were too short and proper diffusion $W_2^2 - W_1^2$ could not take place. The water separated from the rear of the runner blades and did not fill the channels; $W_2^2 - W_1^2 = C_r \leqq 0$ was not fulfilled, and the typical suction effect was not obtained. In the three-walled hypothetical channels of the propeller-shaped under-pressure turbine, and thanks to the fourth hypothetical wall, the surface of discontinuity, the diffusion $W_2^2 - W_1^2 = C_r \leqq 0$ is accomplished with a liberal leeway at the disposal of nature to adjust itself and to recompense the designer with a flexible efficiency. Summing up, it may be stated:

1 Not every propeller turbine is an under-pressure turbine, but the most efficient form of an under-pressure turbine runner is that of a propeller.

[3] See U. S. Patent 1,347,578, July 27, 1920.

2 An under-pressure turbine deals with negative pressures and is therefore accordingly limited in its practical application as regards head and setting, from the point of view of cavitation, vibration, and stability. However, application to higher heads would be possible and cavitation (vibration and instability) could be avoided if the turbine is so set that the actual piezometer pressure p_r at the throat does not approach the vapor-point pressure. If a propeller of the under-pressure type could be designed physically strong enough for the power thus developed, there is no reason why it could not operate satisfactorily at a high head, provided the foregoing requirement of setting is fulfilled.

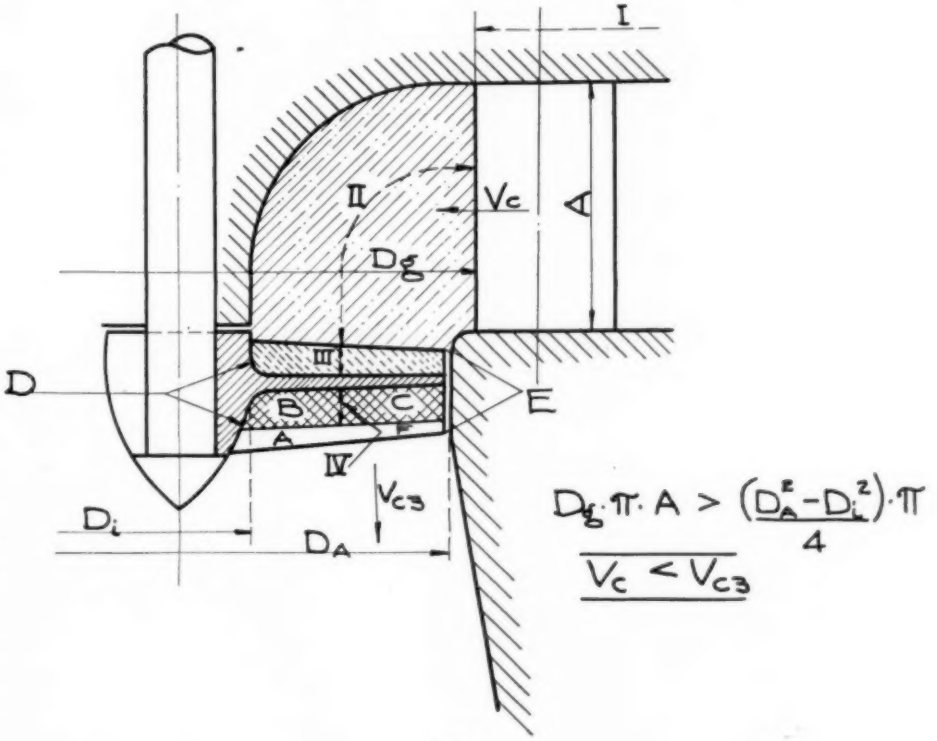

FIG. 2

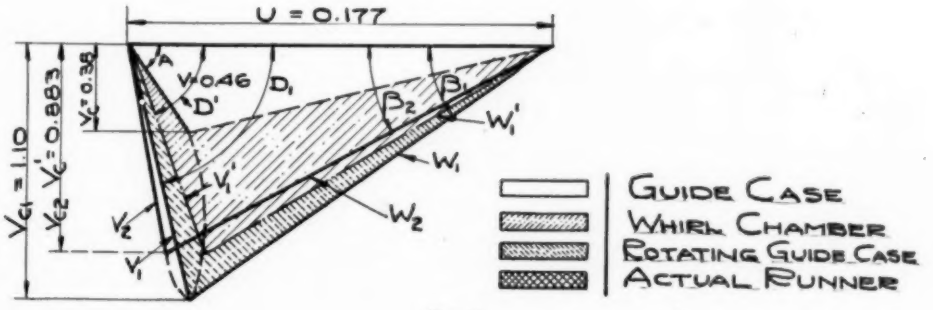

FIG. 3

3 Since the fundamental conditions involving cavitation are now sufficiently known, and since the forces producing cavitation are so destructive that any practically applicable material so far known succumbs, there is no safer way of avoiding cavitation than to keep away from the conditions which are certain to cause the cavitation; and these are high specific speed and high suction head.

Losses of Pressure Head Due to Sudden Enlargement of a Flow Cross-Section

By DR. H. C. SCHUTT,[1] NEW YORK, N. Y.

The exactness of the Borda-Carnot equation for the losses of energy in a liquid medium passing a discontinued cross-section—that is, a sudden enlargement—is discussed, the same formula is derived, based on one of the main principles in dynamics, and a report is given of experiments[2] proving the validity of this formula.

SYMBOLS

V = average velocity in section
p = intensity of pressure
A = area of cross-section
H = total head
Z = elevation head
h = lost head
h_1 = lost head due to friction
h_2 = lost head due to enlargement
g = acceleration due to gravity
γ = specific weight
η = coefficient.

THE motion of a liquid medium through a pipe, turbine, or pump is subject to losses of pressure head. There are two main causes of these losses of energy: the friction and the discontinuance of the flow cross-section. A sudden enlargement of a pipe is a typical case of the latter. This problem has been subjected to theoretical study in order to find a serviceable formula, and also subjected to experimental research to prove the correctness of the theory.

The Borda-Carnot equation

$$h_2 = \frac{(V_1 - V_2)^2}{2g}$$

gives a value for these losses, but there are divergent opinions as to its validity in all practical cases. An engineer generally applies this formula without a correcting coefficient. The reason may be that he has never encountered any appreciable deviation of his practical experience from his calculations or that the simplicity of the formula appeals to him and makes him inclined to trust those authors of treatises on hydrodynamics who advocate the unmodified validity of the Borda-Carnot equation.

But many authors recommend the correction of the formula by an experimentally determined coefficient as great as 1.1, 1.2, and even 1.3. The existing vagueness of this important and frequently applied formula led to the writing of this paper as an attempt to arrive at a more definite solution of this problem.

Borda[3] was the first to understand the mechanical process and to find a mathematical solution. His formula in the version of Carnot is still valid in modern hydrodynamics. Borda did not exclusively deal with these losses in his paper as the title already indicates; he rather determines the time that it takes to fill a submerged vessel with liquid through an orifice in the bottom. (See Fig. 1.) He correctly develops a differential equation introducing losses due to the sudden enlargement of the flow cross-section from A_1, the area of the orifice, to A_2, the area of the vessel. He assumes water as an inelastic medium and applies the mechanical law for the inelastic shock of solid bodies. As in modern physics water is still defined as incompressible and inelastic, thus justifying his assumption, and as he experimentally verified his formulas and obtained a remarkable conformity of theory and experimental results, there is reason enough to take the unrestricted validity of the formula

$$h_2 = \frac{(V_1 - V_2)^2}{2g}$$

for granted and rather examine the details of those experiments

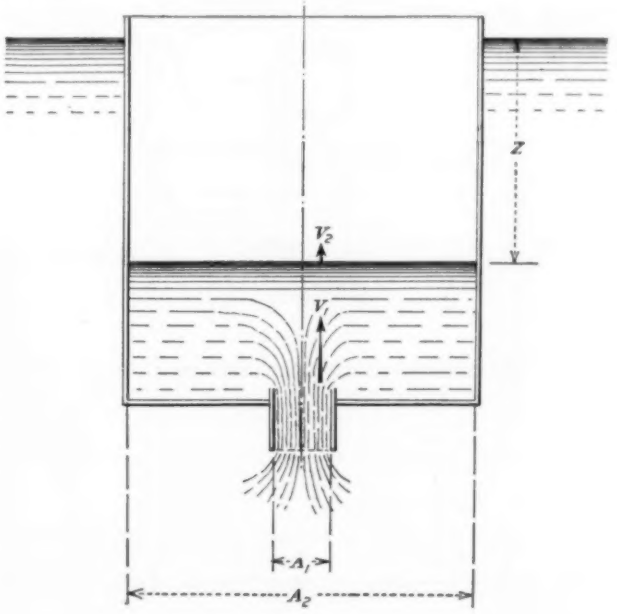

FIG. 1

apparently proving the necessity of correcting the Borda equation by a coefficient

$$h_2 = \eta \frac{(V_1 - V_2)^2}{2g}$$

Gibson[4] expresses η as dependent on the ratio of enlargement and the smaller diameter by the experimentally found relation

$$\eta = \frac{102.5 + 0.25\,m - 2D_1}{100}$$

where $m = \frac{A_2}{A_1}$ and D_1 = the smaller diameter. This equation gives a value for η in an experimental case reported below, where

$$m = 2.84;\ D_1 = 3.75;\ \text{and}\ \eta = 0.957.$$

[1] Mechanical Engineer.

[2] The experiments have been made in the laboratory of the Institute of Hydraulics in Munich, Germany. The Transactions of that Institute for 1926 contain a report of the test results.

[3] Memoire de l'Academie royale des Sciences, Paris, 1766: Memoire sur l'ecoulement des fluides par les orifices des vases.

[4] A. H. Gibson, "Hydraulic and Its Applications," p. 86.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The validity of this auxiliary formula is wisely limited for a certain range of m and D_1, but significant is the fact that η depends on the ratio of enlargement and can even obtain a value less than 1. Generally the opinion is to give η a value greater than 1.

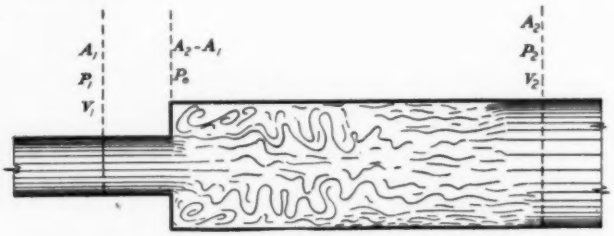

FIG. 2

Considering the mere physical occurrence of a flow of water through a suddenly enlarged pipe (see Fig. 2), there is to be included the process of the mixing of the jet leaving the smaller section with the slower moving water of the larger section. This process takes place over a greater length of the flow direction; and the actual influence of the enlargement can only be discovered by examining two cross-sections—one just before the enlargement and one far enough behind where the mechanical process has surely terminated.

Under this presumption the formula can briefly be developed in the following way. The losses are:

$$h = h_1 + h_2 = H_1 - H_2 \quad [1]$$

$$h = \frac{P_1}{\gamma} + \frac{V_1^2}{2g} + Z_1 - \left(\frac{P_2}{\gamma} + \frac{V_2^2}{2g} + Z_2\right) \quad [2]$$

$$h = h_2 = \frac{p_1 - p_2}{\gamma} + \frac{V_1^2 - V_2^2}{2g} \quad [3]$$

omitting the friction losses h_1, as they can easily be eliminated by experiments, and making $Z_1 = Z_2$ by choosing a horizontal arrangement.

Furthermore, it is according to a law of mechanics that the sum of the forces in the direction of motion causes the change of the impulse

$$A_2 p_2 - A_1 p_1 - (A_2 - A_1)\, p_0 = m(V_1 - V_2) \quad [4]$$

where m is the mass of the liquid flowing through per second

$$m = A_2 \frac{V_2}{g} \gamma \quad [5]$$

Assuming $p_0 = p_1$, which has especially to be verified by the experiments, then is

$$A_2(p_2 - p_1) = \frac{A_2 V_2}{g} \gamma\, (V_1 - V_2) \quad [6]$$

$$\frac{p_2 - p_1}{\gamma} = \frac{V_2(V_1 - V_2)}{g} \quad [7]$$

and combining [7] and [3]

$$h_2 = \frac{V_1^2 - V_2^2}{2g} - \frac{V_2(V_1 - V_2)}{g} \quad [8]$$

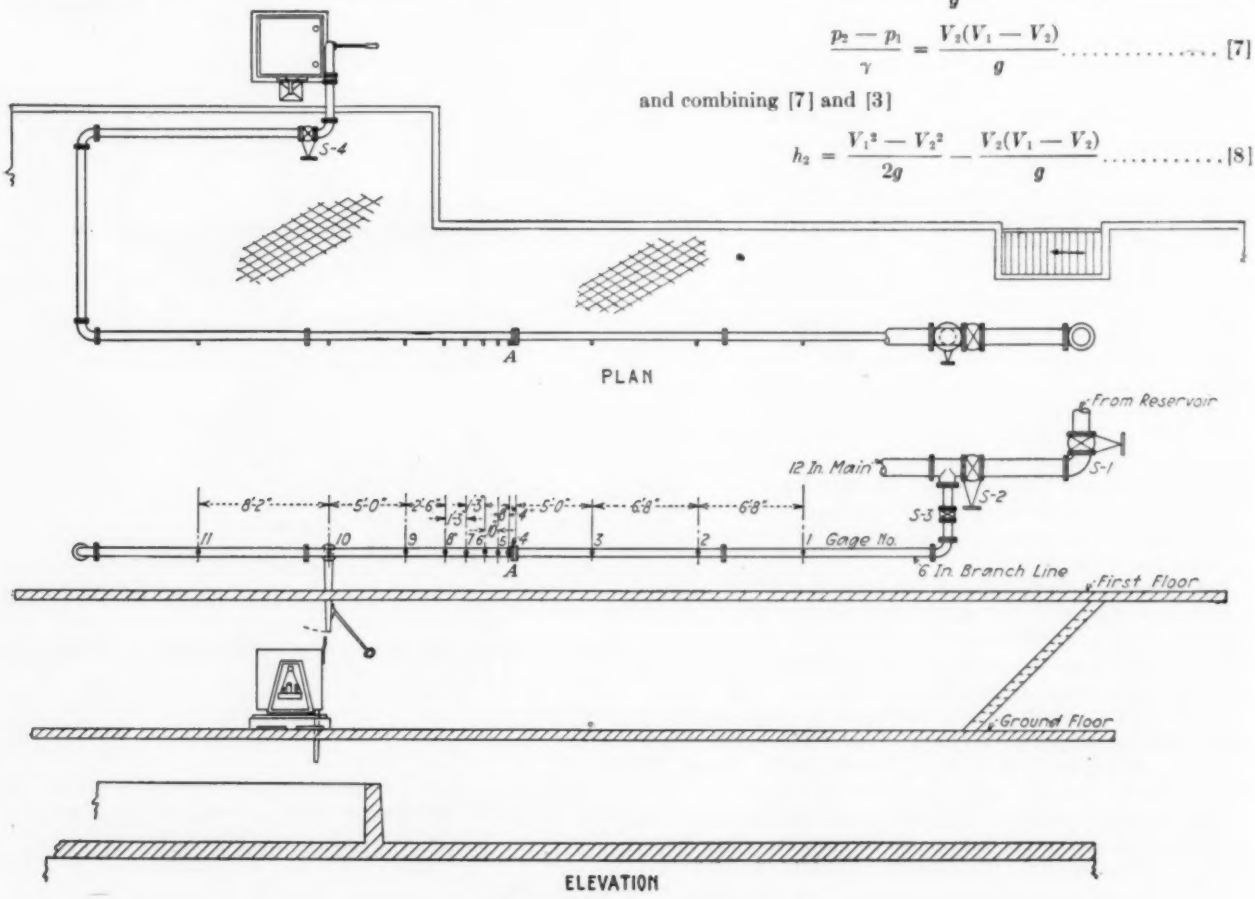

FIG. 3 EXPERIMENTAL ARRANGEMENT

$$= \frac{V_1^2 - V_2^2 + 2V_2^2 - 2V_1V_2}{2g} \quad [9]$$

$$= \frac{(V_1 - V_2)^2}{2g} \quad [10]$$

This is indeed the Borda-Carnot equation again.

Experiments have been made by the author of which a brief report is given below.

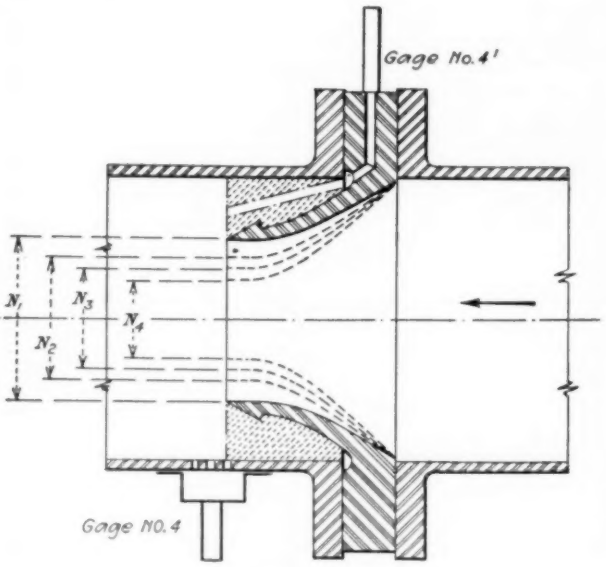

FIG. 4 SECTION AT *A*, FIG. 3

The experimental arrangement is shown in Fig. 3. The water is supplied by a high reservoir through the 12-in. water main passing the valves *S*-1 and *S*-2, and taken off by a branch line through the valve *S*-3. The reservoir has a sectional overflow, thus guaranteeing a constant head, which is throttled down by the three valves equally in order to obtain an undisturbed flow in the branch line, the actual research line with the observation spots numbered 1 to 11. At *A* a nozzle (Fig. 4) is laid in the line between two flanges, thus effecting a contraction of the flow cross-section and consequently the desired sudden enlargement. The special shape of the nozzle is to avoid any "vena contracta" at the mouth of the nozzle. The location of the observation spots is chosen for obtaining the best knowledge of the pressure gradient and consequently of the actual losses. Open water columns are used as pressure gages; the connection to the pipe is shown in Fig. 5. The quantity is measured by weight to determine the average velocity V_2.

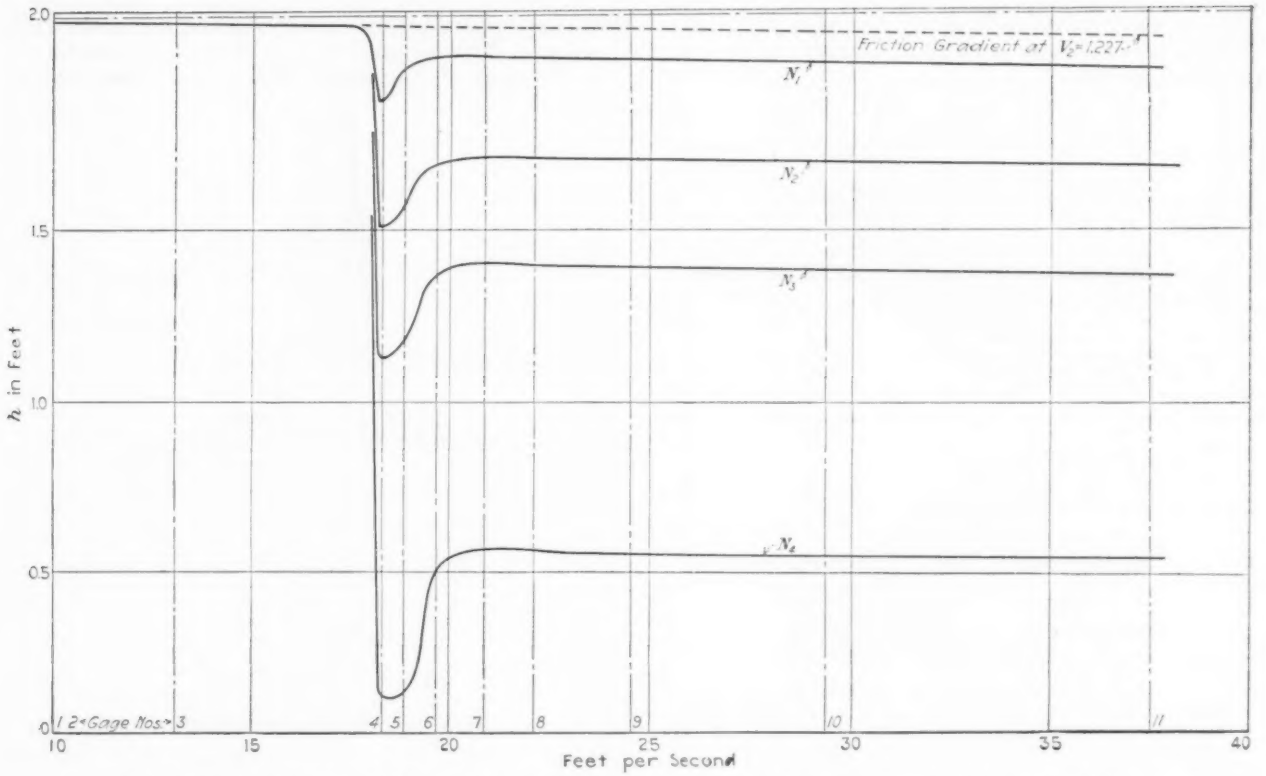

FIG. 7 PRESSURE-HEAD GRADIENT FOR THE FOUR NOZZLES AT THE SAME VELOCITY V_2 = 1.227 FEET PER SECOND

Experiments have been carried out with four nozzles. Table 1 shows some general data.

The experiments have been repeated with the space behind the nozzle filled with gypsum in order to ascertain any possible influence of this space upon the losses.

The experimentally obtained losses consist of the friction losses and those due to the sudden enlargement. In order to eliminate the friction losses, first the friction gradient of the pipe, sections 1 to 11, has been determined within the range of the velocity applied. In Fig. 6 the observed friction gradient as well as the total pressure-head gradient is shown for nozzle N_1 at three different velocities, and it is explained how the immediate test results have been valuated. Fig. 7 gives the pressure gradients for the four nozzles at the same velocity.

A summary is given in Table 2 for the two nozzles N_1 and N_2 of about 400 tests which have been made and which are graphically and numerically analyzed. Observations 1_1 to 1_{11} designate the static-pressure head at the corresponding gages 1 to 11.

In addition to Table 2, Fig. 8 shows the test results. It may be noted that the validity of the Borda-Carnot equation for the practical computation of any losses due to a sudden enlargement of the flow cross-section is proved. The deviations are not more than 1.5 per cent, as these experiments have shown, and even these deviations may be ascribed partly to mere irregularities in the observation, as they are sometimes negative.

The assumption that $p_0 = p_{11}$, as made when deriving the

							Average less than	1.0

formula, is correct, as it has been especially observed in each case at gages 4 and 4[1]. There is no influence of the ratio of enlargement nor an effect of the dead-water space in back of the nozzle upon the losses.

As can be seen in Figs. 6 and 7, the influence of the nozzle upon the current—that is, the effect of the sudden enlargement—is still perceptible at the observation spot 8, or about ten times the pipe diameter away from the enlarged cross-section. In this fact there may be an explanation for the opinion of several authors that experiments show the necessity of the correction of the formula by a coefficient. In many experimental cases the regain of pressure head out of velocity head has not been fully observed by taking the pipe section behind the enlargement too

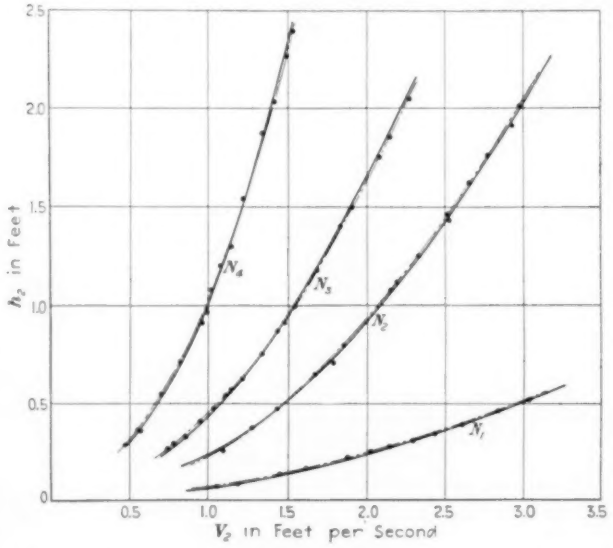

FIG. 8 FORMULA $h_2 = F(V_2)$ ACCORDING TO THE FORMULA $h_2 = \frac{(V_1 - V_2)^2}{2g}$

(The dots on the curves are placed at the points found by experiments.)

short. This was, for example, the case with the experiments of H. Baer.[5]

In hydraulics and especially in aerodynamics the most valuable knowledge can be gained only by analyzing a process qualitatively first and then making quantitative tests. This is the course generally taken in modern engineering science. Borda did not know exactly the character of the physical process taking place in case of a sudden enlargement of the flow cross-section; but his experimental arrangement seemed to prove his assumption accidentally. His explaining the process as a shock of inelastic masses may have prevented this important matter in hydraulics from really being qualitatively examined.

Though these experiments have furnished sufficient evidence as to the validity of the Borda-Carnot formula for technical calculations, the author thinks it worth while to make tests with a similar arrangement, where a greater accuracy can be obtained, and special attention given to the velocity distribution in the different cross-sections. Such experiments may at the same time complete our knowledge of the properties of flow nozzles as fluid meters.

Discussion

BLAKE R. VAN LEER.[6] This paper is a partial translation of the article "Versuche zur Bestimmung der Energieverluste bei Plotzlicher Rohrerweiterung," pages 42–58 of vol. 1, "Mitteilungen des Hydraulischen Instituts der Technischen Hochschule Munchen," which work Dr. Schutt performed under the direction of Dr. Thoma as part of his work for his Doctor of Engineering degree.

The value of the publication of this article lies in the fact that it directs the attention of American engineers to additional experimental data upon the subject and gives this data in English units, whereas the article referred to gives it in the metric system. Also, the only other published results with which I am familiar are those published years ago by H. W. Archer in the Proceedings of the A.S.C.E., vol. 39, no. 3, March, 1913, who obtained the equation:

$$h^1 = 1.098 \frac{(V_1 - V_2)^{1.919}}{2g}$$

I think the appraising of the equation which Dr. Schutt discusses is shown in a statement by Prof. J. N. LeConte in his book "Hydraulics," McGraw-Hill Co., 1926, p. 98: "Hence, the loss due to a sudden enlargement is numerically equal to the square of the difference of the velocities divided by $2g$. The result is well borne out by experiment. . . . When a sudden enlargement exists in a pipe line, the loss can be entered in the energy equation by means of the expression $(V_1 - V_2)^2/2g$ without the use of a k-coefficient."

Progress in Hydraulics

Contributed by the Hydraulic Division

Executive Committee: L. F. Moody, *Chairman*, B. E. White, *Secretary*, H. L. Doolittle, W. M. White, and Ely C. Hutchinson

MUCH the greater part of the developed and undeveloped water power of the United States and Canada is owned by public-utility companies. For this reason, the consolidation of electrical service and holding companies into fewer and larger business organizations is a development which vitally affects the field of hydraulic engineering, because it affects the economics of hydroelectric power. These effects are both favorable and unfavorable.

The much wider, and possibly almost universal, adoption of the so-called promotional or inducement form of rate, together with the probability of uniform rates for different classes of service throughout areas of considerable size, will accelerate the demand for electrical service, thus creating a much larger market to be supplied.

On the other hand, the much larger and more economical fuel power stations made possible by the consolidated utility groups and the greater demand, have changed the load conditions and lowered the unit costs of energy to a level with which many water powers can no longer compete.

Factors Affecting the Economics of Hydroelectric Power Development

One of the major effects of the increasingly large combinations of utility companies has been upon the economics of many water-power sites, which had hitherto been considered favorably for development. With the vastly increasing markets, the load factor demanded from many sites and plants has been profoundly changed, while at the same time the construction of vastly larger and much more efficient fuel power-generating stations has resulted in a lower competitive cost which many water-power sites cannot meet. A partial solution of this difficulty may possibly be found in a simplification of hydroelectric construction, which may result in lower construction and operating cost. The automatic and semi-automatic plants are types of the tendency in this direction. Likewise, the outdoor or semi-outdoor type of hydro generating station, consisting of one or more units remotely controlled, either from another power station or by variations in forebay water level, are variations of this tendency.

The discovery and development of an important natural-gas field in central California has made it possible to produce steam power in gas-fired installations at a lower cost than previously obtained with oil-fired boilers and many hydroelectric plants. In the opinion of many on the Pacific Coast, it is probable that new hydroelectric developments in that region will be greatly retarded, if not nearly discontinued, for a period of years by this development.

Contrasting with the opinions of some as to the economics of hydro power versus steam power, is the situation reported in the Pennsylvania area, where with all its coal mines a four-fold increase in hydro power installation has taken place within the last six years. Apparently there is still a field for the skilful hydroelectric engineer who makes his designs on the basis of dollar efficiency.

Ample water-storage capacity is becoming an ever more necessary adjunct of commercially efficient hydroelectric development, and many sites heretofore considered unavailable are constantly being found to be commercially feasible.

There is said to be an increasing tendency to purchase hydraulic equipment on the basis of price alone. It seems hardly necessary to call the attention of engineers to the fact that there is still room for advances in design and construction, which can only be brought about by continued study and experiment, at some one's cost. In this field the logical source of such experimentation is the manufacturer. Price cutting below the level of a fair profit will inevitably dry up these springs from which improvements flow, and at the same time introduce the hazards that go with poor design and construction, and details slighted or omitted to save cost, with consequent lessened efficiency and increased maintenance costs.

The outstanding tendency is to build larger and larger units, limited only by the quantities of water available from season to season, or by the limitations of mechanical design or of transportation. This has been made commercially feasible by the larger markets, and by the large aggregations of available capital resulting from the great groupings of utility organizations which have recently been brought about and are still continuing their growth.

Governmental Regulation and Supervision of Utilities and Structures

There are many who view with concern the increasing burden constantly being thrust upon utility concerns, who are by far the largest aggregate owners of water powers, and upon water-power development in particular, through the medium of legislation and administrative regulation. The margin of cost between fuel-generated and water-generated power and energy in nearly all parts of the country has been cut to such small dimensions that the taxes and license fees recently imposed have made the development of additional water power almost, if not quite, a hopeless proposition, so far as competition with steam-, oil-, or gas-generated energy is concerned.

The public authorities, as represented by the state engineers, etc., are exercising a greater degree of control and supervision over the design and construction of high dams than ever before, as a result of such failures as that of the St. Francis Dam.

Governmentally Owned Hydro Plants and Projects

During the year, the largest hydro power development thus far projected, that at Boulder Canyon, on the Colorado River, has been authorized. In connection with it there will be constructed the highest dam in the world, impounding probably the largest artificial body of water in existence. The construction of this project involves many difficult problems of engineering design and construction, as well as many problems arising out of its ownership, construction, and operation by the Government, the sale of its output to utility companies, municipalities, etc., and the transmission of the energy output to great distances.

The disposal of the Muscle Shoals power plant, or of the energy thereby produced, is still under consideration. Likewise the status of the combined St. Lawrence River power and navigation development is practically unchanged, with little to indicate that any definite steps will be taken toward its construction at an early date.

Model Testing

Turning to the more technical field, the subject of model testing, or the experimentation with small models of proposed conduits, machines, or structures, received a great impetus through the publication of John R. Freeman's book on "Hydraulic Laboratory Practice." This monumental work has brought the subject and its possibilities vividly to the attention of many engineers and executives who have hitherto not realized them. It is not surprising, therefore, that model testing, on a greatly accelerated scale, is now going on.

An increasing use of model testing is being made in the investigation and design of the water passages leading to turbine units. Many power companies are finding it well worth while to investigate the possibilities of variations from the accepted forms of intakes and water passages, or those designed by the ordinary rule-of-thumb method, as in the past. In some cases very large savings in earth or rock excavation have been made. In others, more efficient structures have been produced with the same volumes of masonry, or equal efficiency obtained with structures of decidedly less cost. These tests have also revealed the surprisingly large influence of small bends, and other variations in cross-section and alignment, upon the efficiency of the units, the elimination or alteration of which paid very handsome dividends upon the cost of the tests.

Mr. Freeman's book having been written primarily to describe the numerous European laboratories and their methods, and in advocacy of an American national hydraulic laboratory, it is perhaps natural that many received from it the impression that the laboratories in this country are decidedly inferior. It is undoubtedly true that there are but few of them which are equipped to carry on many of the investigations now being regularly made across the Atlantic. It is fair to say, however, that there are in this country laboratories which possess every requisite for the making of any type of hydraulic experiment for which any probable need may arise.

At least one of the university laboratories has been engaged for a considerable length of time in making experiments involving river hydraulics, and more particularly in developing suitable spillways, energy-dissipating devices, channels, etc. A particularly large model of a section of approximately 1½ miles of the channel of the Columbia River, at, above, and below Rock Island, has been constructed at the Alden Hydraulic Laboratory, Worcester (Mass.) Polytechnic Institute and experiments are now being made to determine the best type of dam, number of gates, etc. to effectively control the flow at high flood stages.

While the discussion of the proposed National Hydraulic Laboratory is continuing and little apparent progress is being made, various universities and governmental and private laboratories have been newly established or have been expanding their facilities. Some have expressed the belief that the parceling out of important studies among laboratories scattered throughout the country would exercise a profound influence for good upon the practice of hydraulic engineering. It is held that the much wider dissemination of the knowledge of and experience in model testing and its relation to the results with full-sized structures will stimulate research and accelerate the discarding of time-honored, rule-of-thumb methods of design.

In the field of model testing also, a method has been worked out by the engineers of the U. S. Reclamation Service, Denver, Colo., for the design of arch dams by the trial-load method. This is the first method thus far proposed in which the shape of the canyon is taken into consideration in the determination of stresses.

This is, no doubt, a direct outcome of the work of Engineering Foundation's Committee and associates at the Stevenson Creek arch dam, California, and of the corresponding model-arch tests made by Professor Beggs, of Princeton University.

Dams and Accessories

In the recent past, what had been considered minute and unnecessary details of dam construction have been receiving the attention that they deserve. It has been realized that contraction joints should be provided in at least two directions in massive unreinforced concrete masonry, in order to avoid possibly dangerous cracking. New methods of placing concrete, notably the use of articulated belt conveyors and towers, have recently been introduced, thus avoiding the horizontal flow of concrete and the segregation of material. Likewise, the water-cement ratio need no longer be influenced by the consideration that the mixture should be plastic enough to flow readily in chutes.

Recent investigations by means of telemeters imbedded in large concrete masses, such as dams, have revealed the existence of high local temperature stresses. Investigations in regard to this matter are now in progress at the Shaver Lake Dam, in southern California, and at Bull Run Dam, in Oregon.

The use of electric-arc welding has been extended to the construction of racks and gates of various types, producing structures of better design and greater strength and resistance than were heretofore obtainable with the usual bolted or riveted connections.

The increasing use of the controlled spillway instead of the formerly almost universal fixed spillway has also resulted in a marked reduction in the cost of many projects. A particular advantage is that of avoiding the occasional flowage of large areas of land, at times of flood, which are normally free of water, thus reducing the cost of flowage land and the damages from flooding.

Measurement of Water

There is also reported a markedly increasing tendency among power companies to have their units tested for efficiency under operating conditions. There is also a rapidly accelerating tendency to rate some hydraulic section adjacent to each unit for use in connection with a flow recorder, so as to be able to maintain a continuous record of water flow for comparison with electrical output, as a check against efficiency, and also to maintain a continuous record of stream flow. The latter element is often of very great importance, since the construction of many hydro plants drowns out the excellent gaging stations maintained under the supervision of the U. S. Geological Survey or state engineering departments, thus causing the loss of all reliable means of measuring the flow of the river.

Where the units are equipped with flow recorders, the forebay with a water-level recorder, and in addition a record is kept of spillway-gate or flashboard openings, it is possible to duplicate with reasonable accuracy the records formerly kept at river-gaging stations. The value of these records in checking station performance, as well as in planning future development, is hard to estimate.

In the field of pure hydraulics there should be mentioned the Parshall venturi flume developed by Ralph L. Parshall, Mem. A.S.C.E., of the U. S. Department of Agriculture, Fort Collins, Colo., for the measurement of the flow of water in open channels. This flume is extremely simple, as well as very accurate. Mr. Parshall has also conducted valuable experiments for the determination of the relation of the evaporation from large water surfaces to that from various kinds of evaporation tanks.

Adjustable-Vane Turbines

In the field of hydraulic machinery, the most notable development of the past year has been the installation, by the S. Mor-

gan Smith Company, at the Devil's River plant, in Texas, of a Kaplan-type high-speed turbine, whose blades are adjustable by means of the governor. A second unit of this kind is to be installed by the Wisconsin Power & Light Co. at their Rockton Plant, and several additional units are now being built for the Nova Scotia Power Company. High-speed runners, with hand-adjustable blades, had been previously installed at the Chippewa Falls Plant of the Northern States Power Company, and more are being installed by the Dominion Engineering Works, Ltd., Montreal, a subsidiary of I. P. Morris & De La Vergne, Inc., in the Back River project of the Montreal Power & Light Company, near Montreal, Canada, as well as at the Upper Hook Falls development of the Nova Scotia Power Commission. Two of the Back River units have been built with ejectors, which are expected to increase the output of the machines approximately 1000 hp. each during periods of high water. This type of installation permits a much more efficient use of a variable flow on a variable head than turbines with fixed vanes, and will undoubtedly have a marked effect upon the economics of many low-head, run-of-river projects.

High-Speed Propeller-Type Turbines

The successful application of propeller-type turbines to heads as high as 60 ft. has been demonstrated by the installation of a fifth 28,000-hp. I. P. Morris unit in the Great Falls plant of the Manitoba Power Company. Here the head varies from 17½ ft. to 60 ft. Control of cavitation was secured by providing sufficient blade area to give liberal values and distribution of pressure intensity.

Impulse Turbines

In the field of impulse turbines, improvements have been made in their efficiency by improving the shape of the buckets and nozzles, and by the addition of baffles to prevent water from entering the housing.

There has recently been put into operation an impulse turbine of 32,200 hp., at 143 r.p.m., under 800 ft. head, of the double overhung impulse type. The impulse wheels are each 176 in. in diameter, or 21 in. greater than that of the largest previous units. The jets impinging on the buckets are 14 in. in diameter. This unit was installed by the Allis-Chalmers Company, Milwaukee, Wis., in the San Francisquito No. 1 Plant of the Bureau of Power and Light of the City of Los Angeles, Cal.

In the Big Creek No. 2-A plant, of the Southern California Edison Company, two double overhung single-nozzle impulse units of 56,000 hp. capacity, under 2200 ft. head, were installed, one by the Pelton Water Wheel Company, San Francisco, Calif., and the other by the Allis-Chalmers Company. These machines are of record capacity for this type of turbine, and have developed a maximum of 70,000 hp. each over long periods.

The Pelton Water Wheel Company also installed two 35,000-hp., double overhung impulse turbines at the Bucks Creek plant of the Feather River Power Company, where an efficiency of 85.05 per cent was obtained. Maximum outputs of 40,000 hp. have been developed.

Active experimentation is being carried on by the Allis-Chalmers Company and the Pelton Water Wheel Company, with the object of still further increasing the efficiencies of impulse units.

Reaction Turbines

During the year, the highest-head plant in the East was placed in operation: namely, the Waterville Plant of the Carolina Power & Light Company, at Waterville, N. C., operating under 861 ft. head. The principal features of this plant are a constant-angle arch dam 180 ft. in height, a 14-ft. tunnel drilled in solid rock, approximately 6 miles in length, and the use of three S. Morgan Smith Co. reaction turbines of 49,000 hp. each.

A 44,000-hp. Pelton turbine, operating under 715 ft. head, was installed in the Southern California Edison Company's Big Creek No. 8 plant, which showed a maximum efficiency of 93 per cent when tested by the Allen salt-velocity method.

Among the interesting reaction-type units may be mentioned the 8550-hp. unit being constructed by I. P. Morris & De La Vergne, Inc., for the Turners Falls Power and Electric Co., for its Cobble Mountain, Mass., development, to operate under 420 ft. head. This unit will operate in connection with a long pipe line and, to limit pressure rises, the rate of gate closure will be limited by non-removable diaphragms in the governor piping instead of a relief valve. Leakage and waste of water through relief valves will be eliminated and the pressure rise definitely limited by a simple device.

Rubber sealing strips, set into the faces of the upper and lower distributer rings, against which the guide vanes tightly close, are a feature of two 36,000-hp. units, to be installed at the Alabama Power Company's Lower Tallassee development, under 88 ft. head. These strips reduce the gate leakage during the hours when the units are shut down, leaving them in condition for immediate starting up in case of necessity by simply opening the guide vanes, yet economizing the water supply.

Rubber-lined bearings have also proved successful in a number of large units. Bearings 22½ in. in diameter are installed at the Back River plant, Montreal, Canada.

Extensive research in the field of reaction turbines and related structures, such as conduits, draft tubes, etc., is being steadily carried forward in the excellent laboratories of turbine manufacturers, universities, and power companies. As this research proceeds, new and valuable testing equipment and methods, as well as important improvements in and data concerning turbines and accessories, are constantly being developed.

Recent advances in electric-arc welding have made it possible to produce arc-welded plate-steel scroll cases, some of which have been constructed with short, straight tangential sections, and some with bumped plates, which combine the interior smoothness and streamlines of cast-metal scroll cases with the strength and ductility of steel. The very much lighter weight obtainable with sheet-metal cases is reflected in the ease and reduced cost of transportation, and also undoubtedly eliminates the hazard of cracked scroll cases, which have been responsible for a number of serious accidents in hydro power plants.

This type of spiral case has been used by the Allis-Chalmers Company, with two 56,000-hp. vertical units, under a normal effective head of 213 ft. having 16-ft. inlet diameters, and for three 36,000-hp., 390-ft.-head turbines, the latter having been installed in Japan. The flow of water to both of these units is controlled by electric-motor-operated butterfly valves. Other companies have also built turbines with welded-steel scroll cases.

One contributor emphasizes the importance of the satisfactory operation of the Oak Grove, Oregon, 850-ft.-head reaction units as a measure of economy. The space requirements for such a unit are much less than those for impulse units of the same capacity, under the same head, thus economizing in the cost of power-house construction. These and other high-head units have now been in operation for approximately five years, with very satisfactory results, thus confirming the practicability and reliability of high-head reaction turbines, concerning which some doubt was felt at the time of installation.

During the past year the Rocky River pumped-storage hydro development has been put into service and has functioned satisfactorily.

Generators

The development of the umbrella-type generator, at the instance of A. C. Clogher, hydraulic engineer of the Electric Bond

and Share Company, has made it possible to reduce the height of power houses. This type of generator requires but two bearings, the upper a combination thrust and guide bearing, and lends itself to the semi-outdoor type of installation in which a conical hood of sheet metal protects the generator from rain entering at the top, and at the same time permits ventilation to the outdoor air.

In one installation at least, the Norwood Station of the Carolina Power & Light Co., Mt. Gilead, N. C., air washers have been installed adjacent to the generators, not only to remove the dust in the air, but to cool it to such an extent that better ratings and better generator efficiencies are obtainable in hot weather.

The recently developed Kingsbury spherical combined thrust and steady bearing seems to offer possibilities in connection with this design of unit.

Frequency and Load Control

The widespread interconnection of power systems which has occurred in recent years has made the regulation and maintenance of frequency of vastly increasing importance. There have been developed at least two systems of frequency control which have produced very satisfactory results: namely, the apparatus developed by S. Logan Kerr, of I. P. Morris & De La Vergne, Inc., in cooperation with engineers of Leeds & Northrup, and that of the Warren Telechron Company, both of which have been used sufficiently to demonstrate their value.

I. P. Morris-Leeds & Northrup have also developed a load-control apparatus which has functioned satisfactorily to regulate the load carried by two or more units in a station, in order to maintain the highest efficiency upon a given number of units for a given superimposed load. Savings of as much as 8 per cent in energy generated were disclosed by comparative tests with the use of this apparatus, and with the usual methods of hand regulation. The satisfactory operation of this apparatus at the Norwood plant of the Carolina Power & Light Company, has led to its installation at a number of other plants.

Penstocks

Improvements have also been made in the design and materials of penstocks and other accessories for conveying water to the turbines. There is a notable tendency to use welded pipe, especially in Europe where welded bell-and-spigot joints are being extensively utilized. European, and some American, engineers are using welded stiffening angles and other types of reinforcement for penstocks, wyes, branches, etc., increasingly. Anchorages of welded structural steel are also being used to a greater extent.

Improvements in welding equipment and procedure, the recently developed method of non-destructive testing of welded joints, and the improvement in the quality and strength of welded work are creating increased confidence in pipes and special fittings of welded construction. Their greater interior smoothness, the flexibility, ease and speed of design and construction, and their lower cost will undoubtedly bring about a much wider use of water conduits of this type.

Pumps

Research is continuing in the field of centrifugal and screw-type pumps, as is demonstrated by the papers presented before the Society. High-speed propeller-type pumps are growing more popular. Four Moody spiral pumps, of 70,000 g.p.m. capacity, at 400 r.p.m. under 26 ft. head, have been installed by I. P. Morris & De La Vergne, Inc., for the Robins Dry Dock and Repair Company, in New York.

Fish Screens and Fishways

Electrified fish screens have been the subject of intensive and successful experiment in the Northwest during the past year. Their efficacy in preventing fish from traveling into channels where they are unwanted has been proved beyond a doubt, as practically none were found to have passed through them. Further experiments in the way of using them to direct fish to fish ladders or fishways are under way. Likewise experiments on the various types of fish ladders or lifts and other devices for controlling the movements of fish with safety to the finny tribe, are under way, with promise of success. A reasonably satisfactory solution of this problem will remove a very large part of the objection to the construction of high dams on the Pacific Coast, and elsewhere, where anadromous or migratory fishes are present.

Hydrology

In the field of hydrology, promising advances have been made in predicting annual and even seasonal run-off by the use of cyclic methods applied to widely separated drainage areas whose hydrological conditions and topography are much unlike. Attempts to find definite relations between the volume of precipitation in a given rainfall and the succeeding flood peak and run-off, appear to hold some promise of success. A statistical method of relating annual rainfall and run-off has also been developed, whose preliminary trials on watersheds of different characteristics have given very close results. This, combined with the cyclic analysis and forecast of stream flow, holds much promise of furnishing a reasonably close approximation of past run-off where rainfall records exist but stream-flow records are absent; and also of forecasting the flow for the next season and year. With accumulating knowledge and experience, and an increasing number of investigators, further progress along these lines should be rapid.

Progress Report Committee, Hydraulic Division.

An Investigation of a Rotary Pump[1]

By FRANK V. BISTROM[2] and WILLIAM W. WHITE,[2] SEATTLE, WASH.

THE pump tested was a new $1^1/_2$-in. horizontal-shaft rotary pump carrying three vanes and enclosed in a solid casing. Its rated speed was 800 r.p.m., with a capacity of 40 gal. per minute at this speed.

The pump (Fig. 1) consists of three principal parts: (1) the rotor, (2) the vane-linkage parts, and (3) the casing. The rotor, *R* in Fig. 1, is of cast iron shrunk and keyed to the steel shaft *S*. It serves to transmit the power from the shaft to the blades, and rotates about a center above that of the circular pump chamber, but is kept in close alignment by the collar *C*, set on the shaft against the housing at the opposite end of the shaft, and by the bearing *B*, which supports the rotor and its unbalanced load through the cantilever action of the shaft. The rotor is machined to a clearance of 0.002 in. between the top of the rotor and the casing in the size used in these tests, and it is essential to the efficient operation of the pump that this distance be maintained.

The vanes *V*, three rectangular blades, are propelled by the rotor through the action of small half cylinders of brass *A*. These cylinders permit the vanes to rotate about the stub shaft *F*, on the face plate. This stub shaft is centered with the chamber of the pump so that the vanes are held to a positive clearance from the casing at all times. As these vanes rotate with the drive shaft and rotor they slide back and forth through the cylinder an amount equal to twice the eccentricity of the shaft, and they also have a secondary rotative motion of an oscillatory nature. This second rotative effect is utilized to increase the volumetric displacement of the pump by locating the ports at such a position that the space between the blades will be filled with water when the secondary motion has placed them at the maximum angular distance apart.

The casing is of gray cast iron. It provides a housing for a liberal bearing surface on the forward end of the shaft and an outboard bearing at the other end. The face plate and its stub shaft are drilled and provided with alemite cups for lubrication, as is the shaft bearing immediately behind the rotor. The outboard bearing is ring oiled.

The pump was run under varied speeds and head conditions, noting its performance under the conditions of the A.S.M.E. test code, and keeping a close account of its eccentricities for further investigation. To do this a dynamometer was constructed from a General Electric $7^1/_2$-hp. three-phase induction motor by hanging it on roller bearings between two standard shafting journals. From this unit the power was belted to the pump shaft.

Water was drawn from a pump of constant level through a $2^1/_2$-in. pipe and reduced at the pump to $1^1/_2$ in. Discharge was made through the same size piping to a Fairbanks-Morse tank scales, reading the discharge directly in pounds.

Measurements of suction heads were made entirely with a Budenburg mercury gage attached between the pump and the valve regulating the suction pressure (see Fig. 2). The discharge heads, however, required two instruments for accurate measurements. Up to pressures of 7 ft. of water, a water column was attached to the discharge side of the pump, while for higher pressures a calibrated bourdon pressure gage was used.

A Fairbanks-Morse scales provided for the measurement of the dynamometer torque, and used during the first run at 900 r.p.m. proved to be insufficiently sensitive for further work, and were replaced by Fairbanks-Morse platform scales of better construction.

Motor and pump speeds were taken with a hand revolution counter and watch over a one-minute period. Several of these readings were averaged to secure a more nearly correct speed.

The tests were made with clear water at 8 deg. cent. and with the pump operating under its best mechanical condition. Data were taken for given settings of the suction or discharge valves over a ten-minute period. Each test was started by swinging the discharge pipe into the scales tank at a given time, after the valves had been adjusted to give the desired conditions with the discharge in the tank. Care was required because of the syphon effect of the long vertical discharge. During the run, record was

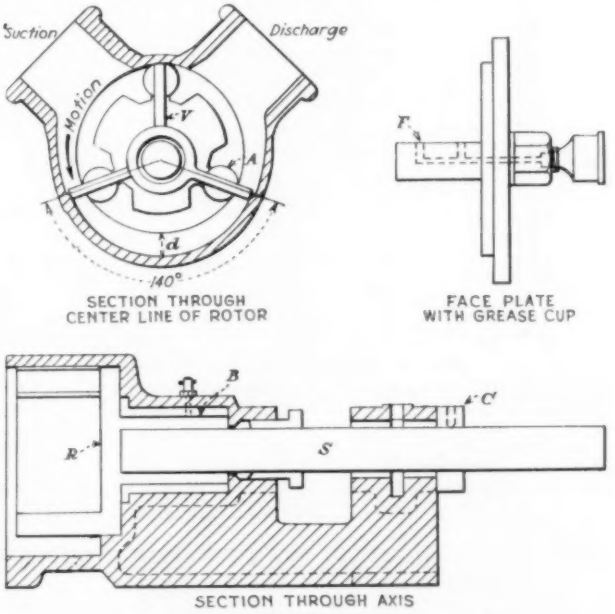

FIG. 1 SECTIONAL VIEWS OF PUMP TESTED

kept of the speed of the motor, of the speed of the pump, of the suction and discharge heads, and of the load on the dynamometer scales. Each of these readings was taken every two minutes together with notes of any unusual performance of the pump.

At the end of ten minutes the discharge was taken out of the tank, the time and the difference in weight of water read and noted. The tank was then emptied back into the sump, the valves adjusted, and the procedure followed as before.

A series of these ten-minute tests taken at the same speed but with varied heads is called a run. Each run shows the results for tests from maximum suction, zero discharge, to 250 ft. of water head on the discharge side. Four runs of 600, 700, 800, and 900 complete the first part of this investigation.

Results of the First Series of Tests

The data computed under the various items is shown in the accompanying graphs. Fig. 7 shows curves for the pump under a suction load at 900 r.p.m. It will be noticed that the point of maximum efficiency, 25 per cent, occurs at a discharge of 36 gal. per min. and under a head of 25.5 ft. of water. The sharp drop

[1] This paper received the A.S.M.E. Student Prize Award for 1929.
[2] Students at the University of Washington.

to the right of this point was accompanied by a severe chattering in the pump which increased as the head was decreased.

Fig. 11 shows the same curves for suction loads at 800 r.p.m., and also indicates the tendency of the chatter at the lower suction heads to lower the efficiency and horsepower output of the pump. It is interesting to note that the volumetric efficiencies of these two runs range between 95 and 100 per cent in the tests in which the chatter was noticed. The 800-r.p.m. efficiency

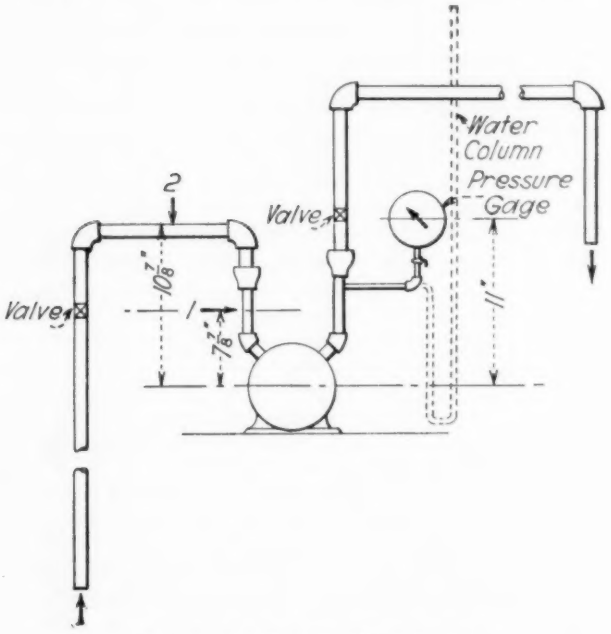

FIG. 2 SET-UP FOR FIRST TESTS

(Mercury column connection No. 1 position used for runs 1 and 2. Position No. 2 used for runs 3 and 4. Pipes 1½ in. at pump, then 2½ in.)

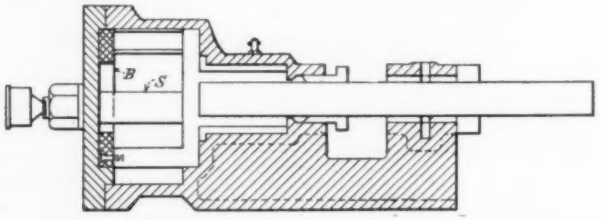

FIG. 3 PROPOSED SUPPORT FOR ROTOR

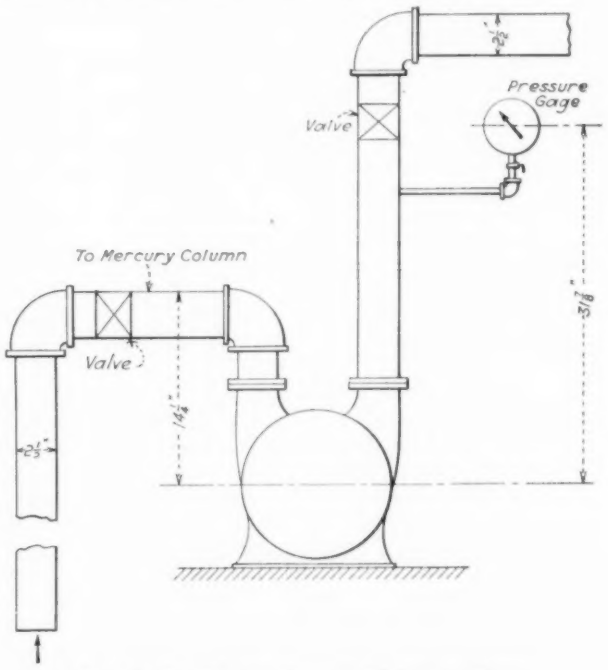
(*B* is a brass ring bolted to rotor, *S* is a stub shaft connected to the face plate.)

curve shows its maximum of 32 per cent at 32 gal. per min. and with a head of 27 ft.

The characteristic suction curves at 700 r.p.m. (Fig. 13) show a marked change in the behavior of the pump. Not only does the hammer occur at the higher heads, but it increases as the heads increase. However, the general shapes of the curves remain the same, except the head and horsepower curves, which show an ability to rise more rapidly as the quantity of water pumped is decreased. This is the equivalent of maintaining the large flow of water over a considerable increase in head and hence the rapid increase in horsepower. The maximum efficiency (29 per cent) is considerably lower at this speed than at 800 r.p.m., although it is still higher than at 900 r.p.m.

Fig. 9, 600 r.p.m., shows further the tendency to chatter at high suction heads. The chatter, however, was general over the entire run, and the head and horsepower curves rise more gradually as the quantity is decreased. The maximum efficiency at this speed is 29 per cent found at 28 gal. per min. output and under 29 ft. of water head.

Fig. 8 shows a run at 900 r.p.m. At this speed the efficiency rises rapidly to a value near 60 per cent, and then remains practically constant over the remainder of the tests. The head-capacity curve indicates no tendency to slip at high heads. There is no record of hammer in the pump during this run.



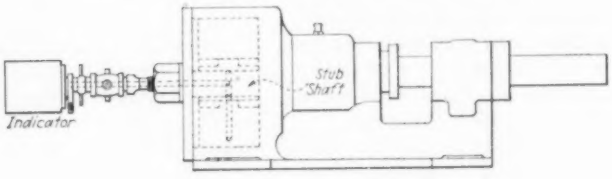


FIG. 4 SET-UP FOR SECOND SERIES OF TESTS

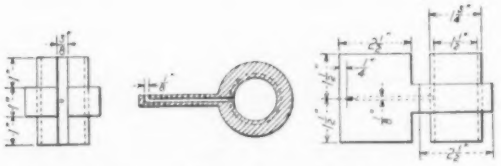

FIG. 5 INDICATOR CONNECTION DETAILS

Figs. 12 and 14 illustrating the pressure runs at 800 and 700 r.p.m., respectively, are typical curves for the pump. The efficiency rises on a curve of decreasing slope to maximums at 39 and 35 gal. per min. output. The 800-r.p.m. run again has the highest efficiency, 72 per cent at the output mentioned. These curves at the higher heads are of interest when considered together with the head-capacity curve, which is practically a straight line under these conditions. Such a consideration indicates that the mechanical losses, not the hydraulic losses, cause the major portion of the loss of efficiency. For, were the losses hydraulic in this region, the rate of decrease of the quantity of water pumped with a given increase in head would increase. Such an action would give the head curve a tendency to turn

upward. Since it does not, the losses must originate in the mechanism of the machine.

The 600-r.p.m. pressure run (Fig. 10) shows the effect of the hammering upon the pump under high heads. From 190 to 270 ft. of water head, some little blade action was noticed. This phenomenon made itself evident in the efficiency curve with a rather rapid drop to a value of 60 per cent at which it remained constant. It is also of interest to note that, during this period, there is only a very slight tendency to increase the drop in the quantity of water pumped for a given increase of head, but that the power taken by the pump shows a tendency to drop below its normal rate of increase.

To make more evident the differences in the operations of the pump at various speeds, the curves in Figs. 15 to 20 were plotted. Fig. 15 shows that with the higher suction loads the output at 800 r.p.m. is a minimum. However, as the suction decreases the output becomes practically proportional to the speed. Here, too, is illustrated the effect of cavitation. Quite evidently cavitation tends to decrease the discharge of a pump working under suction loads. Especially is the effect felt at the higher vacuums. Fig. 16 shows more readily that the capacity of the

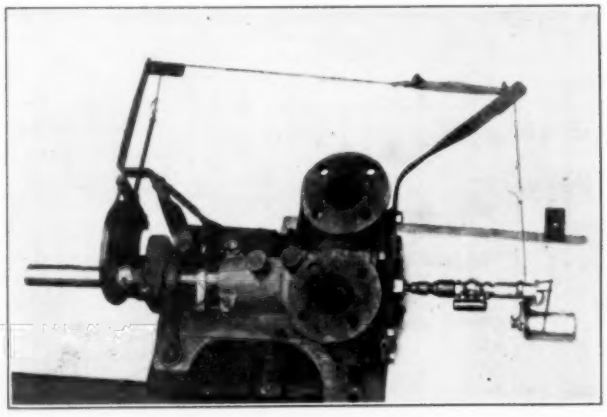

FIG. 6 INDICATOR MECHANISM USED WITH SECOND SERIES OF TESTS

pump under discharge heads is proportional to the speed of the pump, also that the cavitation affects this capacity but very little.

Figs. 19 and 20 demonstrate quite readily the effect of the "hammer" upon the output and input of the pump. In almost every case, both in suction and in discharge loaded runs, the hammer is coincident with an increase in the shaft horsepower and a decrease of the water horsepower. Figs. 17 and 18 show the same thing demonstrated upon the overall efficiency curves. Here also it is seen that the cavitation has a decidedly deterrent effect upon the volumetric efficiency. This effect is most pronounced at the very high vacuums and at the higher discharge pressures. These efficiency curves show too that the rated speed, 800 r.p.m., is unquestionably the most efficient speed. Only at very low suction pressures is the efficiency at 800 r.p.m. below that at any other speed. The volumetric efficiencies for suction runs tend to favor the higher speeds. That of 800 r.p.m. strikes a good mean between these two.

CONCLUSIONS FROM THE PERFORMANCE CURVES

From the performance curves certain conclusions may be drawn embodying not only the essential performance characteristics, but some ideas as to means of improving the performance of the pump as well.

First, regarding the performance of the pump, efficiencies ranging from 60 per cent to 70 per cent over the working range of the pump are exceptionally high. In this connection, it must be remembered that these tests were run under conditions somewhat better than those found in average practice. Es-

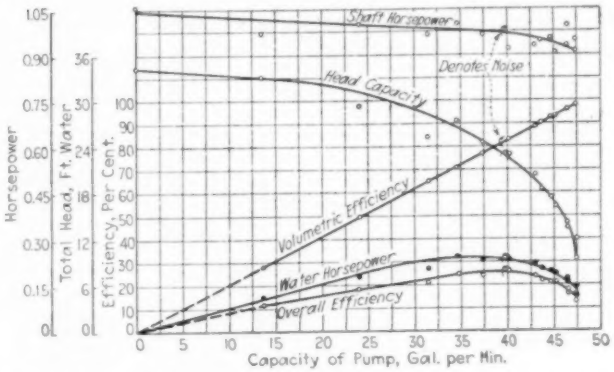

FIG. 7 CHARACTERISTIC CURVES FOR SUCTION RUN NO. 1 AT 900 R.P.M.

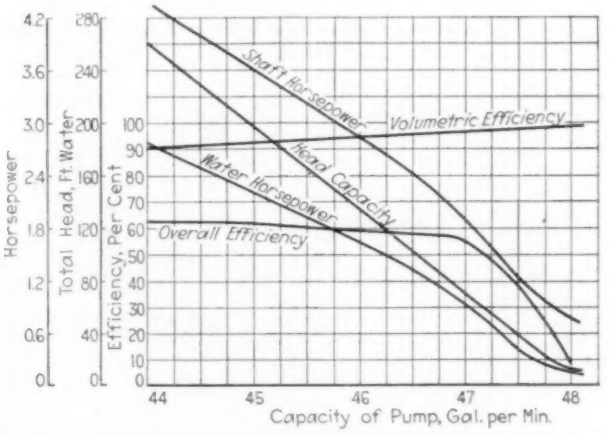

FIG. 8 CHARACTERISTIC CURVES FOR DISCHARGE RUN NO. 1 AT 900 R.P.M.

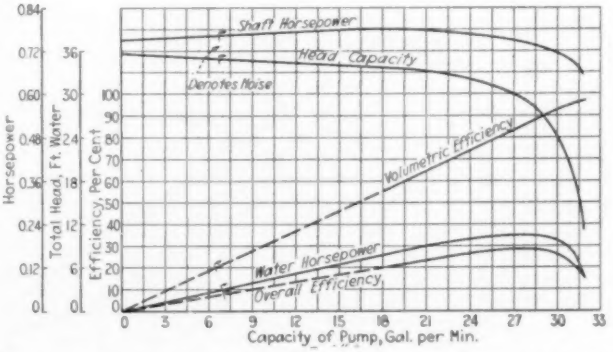

FIG. 9 CHARACTERISTIC CURVES FOR SUCTION RUN NO. 2 AT 600 R.P.M.

pecially is this significant when one considers the high suction heads carried by the pump. Since the pump tested was new and well lubricated, the test should produce results better than those to be expected after considerable wear due to dirty water and long continuous use. However, since the mechanism of the blade assembly holds these blades to a positive clearance from the casing, the wear at the blade ends will not be so severe and the deterioration which will affect most noticeably the efficiency

of the pump will occur in the cylinders and on the shaft which receives the blades.

There is an opportunity for increasing the efficiency of the pump as shown in Figs. 12 and 14. It was demonstrated that the drop in overall efficiency at the higher loads is due largely to an increase of mechanical losses. These losses may have been

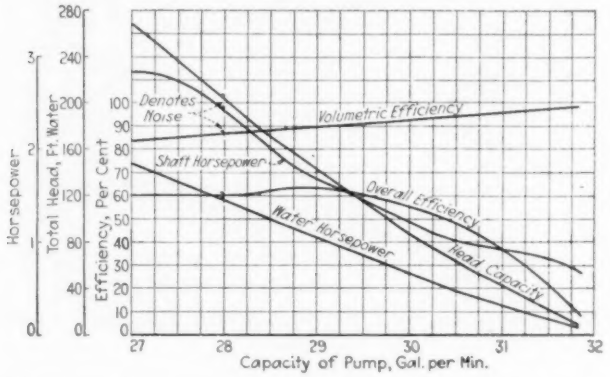

FIG. 10 CHARACTERISTIC CURVES FOR DISCHARGE RUN NO. 2 AT 600 R.P.M.

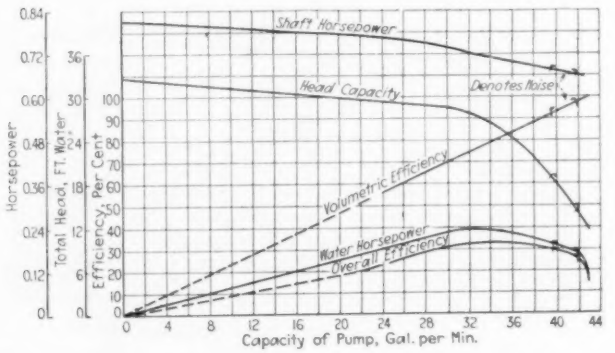

FIG. 11 CHARACTERISTIC CURVES FOR SUCTION RUN NO. 3 AT 800 R.P.M.

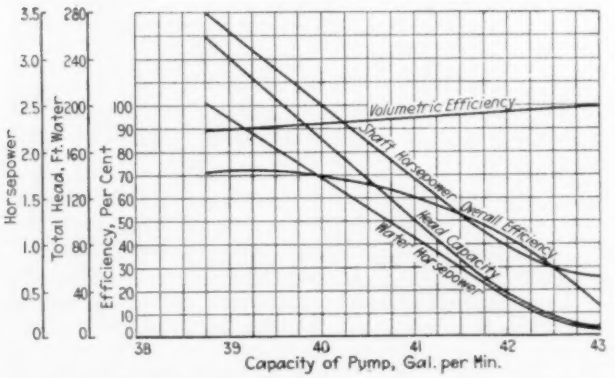

FIG. 12 CHARACTERISTIC CURVES FOR DISCHARGE RUN NO. 3 AT 800 R.P.M.

formed in three ways: First, in the bearings, as a result of the increase of bearing pressure from the belt tension at the higher loads. Second, in the increased bearing losses, a result of the eccentric loading on the rotor, increasing with the higher pressures. Third, the binding action of the rotor back against the rear wall caused by the deflection of the cantilever support of the rotor under the increased eccentric load. This latter and the second loss, to a certain extent, may be relieved by supporting the rotor at both ends. A means of accomplishing this is shown in Fig. 3.

Another means of improving the performance of this pump would be to eliminate, if possible, the hammering that is so prevalent at periods of the pump's operation. This hammering

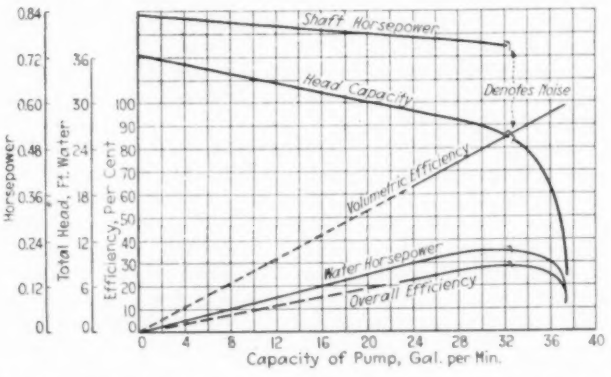

FIG. 13 CHARACTERISTIC CURVES FOR SUCTION RUN NO. 4 AT 700 R.P.M.

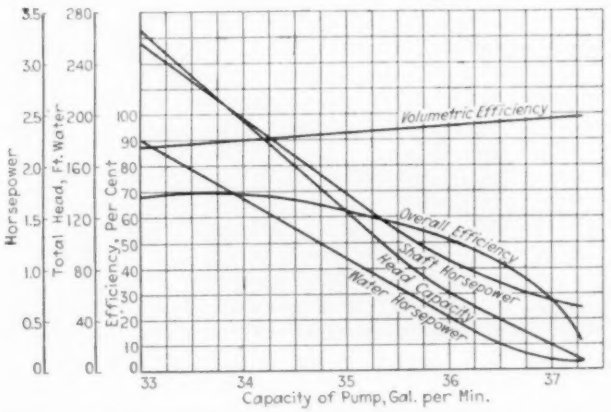

FIG. 14 CHARACTERISTIC CURVES FOR DISCHARGE RUN NO. 4 AT 700 R.P.M.

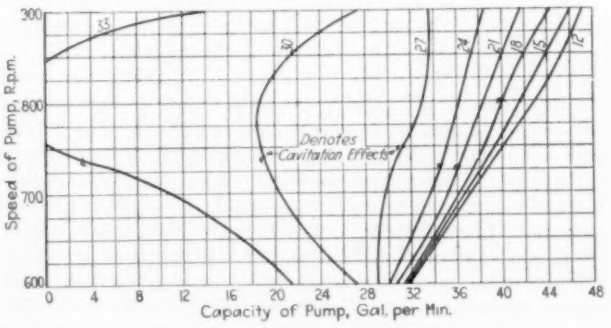

FIG. 15 CAPACITY-SPEED CURVES FOR SUCTION RUNS WITH DEFINITE HEAD CAPACITIES

decreases the capacity of the pump under certain conditions, lowers the volumetric efficiency, and decreases even further the overall efficiency.

Not only does this hammer lower the performance of the pump, but it also is objectionable in the noise that it makes, and difficulty is encountered under such conditions in maintaining tight lines and connections to the pump. Further, the loads im-

posed by such vibration may, under proper conditions, cause a failure in either the pump itself or in its connections. The determination of the nature of this "hammer," its cause, and the means of its elimination are taken up next.

Cause and Remedy for Hammering

To determine the nature, cause, and remedy for the hammering noticed in the tests, apparatus identical with that of the previous tests was used with the exception of:

1 *The pump* was considerably larger than that used in the preceding tests. It had a volumetric displacement of 66.1 cu. in. per revolution against a displacement of 12.5 cu. in. for the

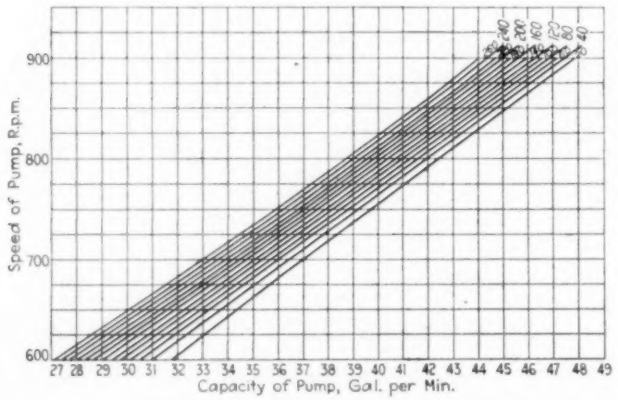

Fig. 16 Capacity-Speed Curves for Discharge Runs With Definite Head Capacities

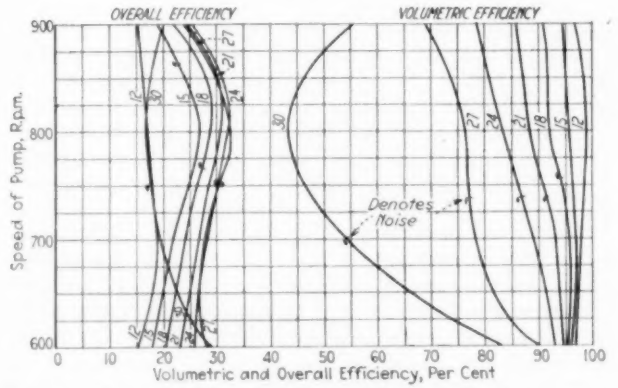

Fig. 17 Efficiency-Speed Curves for Suction Runs With Definite Head Capacities

first one used. The object of using this larger pump was to keep the blade velocities in the two tests as nearly equal as possible, and yet to have the pump running slowly enough in this second investigation to be able to attach an indicator. The casing of this pump was cast with $2^1/_2$-in. flanged connections permitting direct connection of the discharge and suction pipes. (See Fig. 4.)

2 *An indicator* was attached to the pump on the grease stud located in the center of the pump foreplate. This indicator was connected through a hole in the stub shaft to a groove in the shaft under the blade bushing, and from this groove through the blade to a position on its face as shown in Fig. 5. The cylinder movement of the indicator was taken from a cam located on the shaft at the opposite end of the pump. (See Fig. 6.)

The ordinary test was run on the pump as delivered from the factory, taking pressure readings with the indicator. Then such alterations were made in the pump as seemed advisable, and a comparative test was made to check the results of the alteration.

The first tests on the pump were run at a speed of 196 r.p.m.

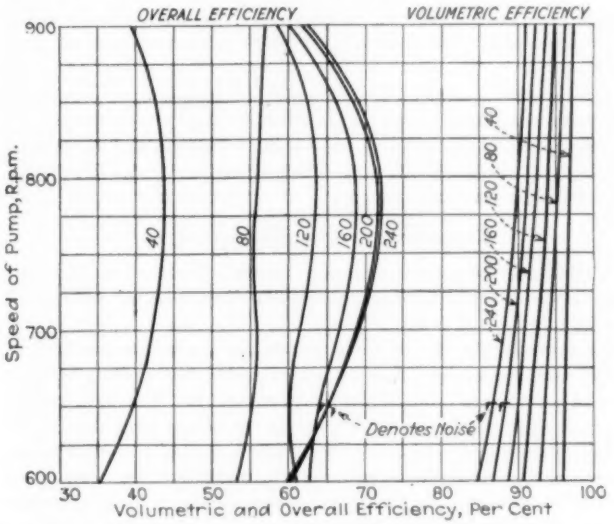

Fig. 18 Efficiency-Speed Curves for Discharge Runs With Definite Head Capacities

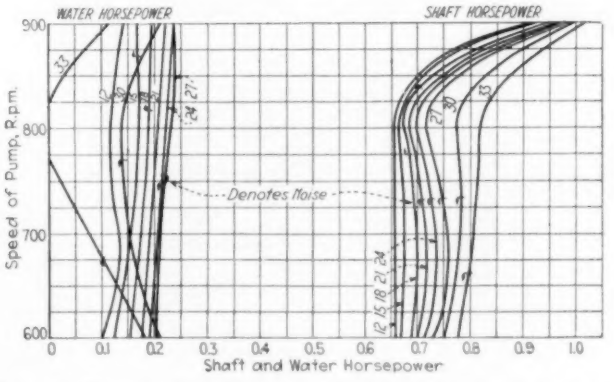

Fig. 19 Horsepower-Speed Curves for Suction Runs With Definite Head Capacities

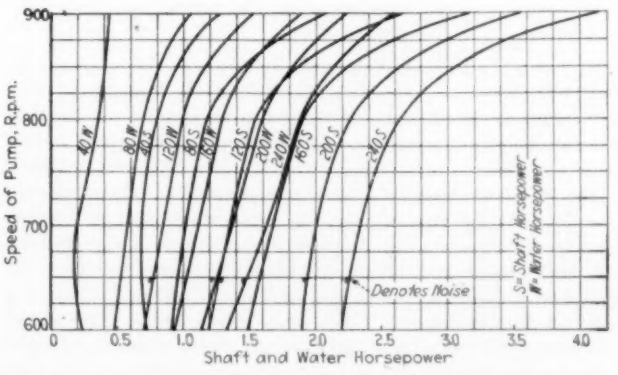

Fig. 20 Horsepower-Speed Curves for Discharge Runs With Definite Head Capacities

A five-minute interval was allowed for each test, during which time readings were taken in the same manner as in the preceding tests, with the exception of the speed determinations. In this case the count was taken over a period of one-half minute. Two

indicator cards were taken during each test as such intervals as to give a fair representation of the conditions. After the completion of the run the tapped blade was removed and reversed; that is, the pressure lead was placed on the suction side of the blade. With the blade in this position, the conditions for each test were duplicated and a "suction" card was taken for that test.

Data were taken under those conditions which would produce the worst hammer in the pump; that is, 27.3 in. of vacuum and varied discharge pressures. For this reason none of the actual values of the data taken in these tests are comparable with values from previous ones.

Results of Second Series of Tests

The data taken were plotted as curves of head capacity, shaft horsepower, water horsepower, volumetric efficiency, and overall efficiency against pump capacity.

Curves *B*, Fig. 21, with the pump set up as delivered, show that the hammering effect increases constantly as the discharge head is built up. There is a tendency also for the head capacity to fall off as this hammer increases at the higher pressures. This behavior indicates hydraulic loss, which is shown further in the drop of the efficiency curve and in the increase of the slope of the shaft-horsepower curve. Quite evidently, the hammering must be associated with loss of efficiency.

The indicator diagrams for this run, Figs. 22 and 23, are plotted to a scale in which each horizontal division represents a 30-deg. movement of the blade. This transformation from the

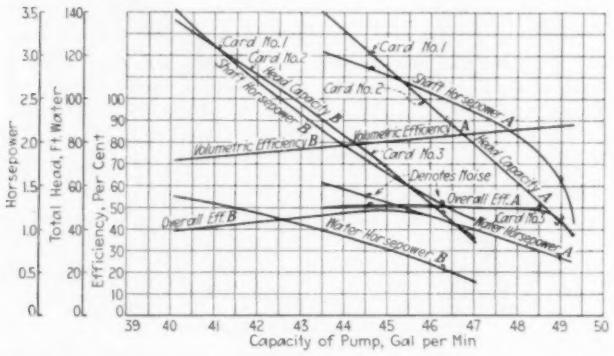

Fig. 21 Comparative Curves for Runs Nos. 5 and 6 at 196 R.P.M.

(*B* denotes run No. 5 before change, *A* denotes run No. 6 after change.)

card was made necessary through distortion of the original card by the harmonic drum motion, and further, the atmospheric line, due to leakage of the valve at the indicator, is not a reliable base for pressure measurements. However, considering the curves from a qualitative standpoint will give quite reliable indications.

Fig. 22 shows the curves from the pressure side. Starting with the left extreme representing top dead center and proceeding counter-clockwise, in the direction of rotation, it is seen that for the first 60 deg. the hole in the blade is covered by the brass cylinders. (See Fig. 5.) From 60 deg. to 140 deg. there is a marked drop in pressure. This drop occurs as the blade ahead of the tapped one moves through the region of maximum displacement increasing the volume between the blades and drawing water, as long as the suction is open, into the displacement chamber. When the tapped blade is at 110 deg., however, this increase of volume ceases. From here on the volume between blades is decreasing. The volume immediately in front of the tapped blade, however, increases until the position 180 deg. is reached. Since the decrease of volume between blades is very slight over the movements near bottom dead center, it seems reasonable to believe that the drop of pressure from 110 deg. to 150 deg. is due to the lag of the water in filling the space immediately in front of the tapped blade. Further, the decreased rate of drop tends to indicate this action, since the rate of increase of area is a harmonic wave and the counteracting effect, the decrease of volume between blades, is also. The difference of the two should give a drop as indicated. At 150 deg. the forward blade opens, dropping full discharge load upon the tapped blade.

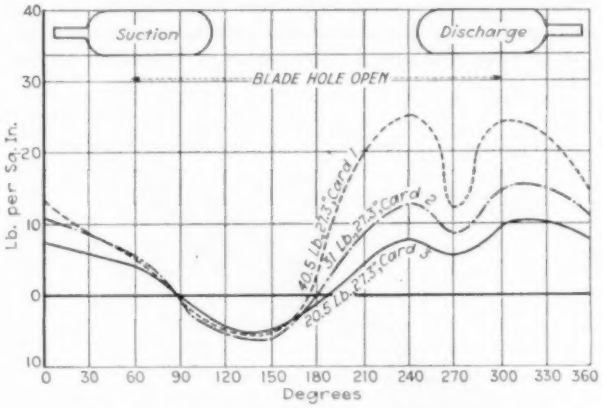

Fig. 22 Pressure Diagram for Run No. 5

The pressure builds up rapidly as the blade passes 180 deg., and the volume immediately before it starts to decrease also. By the time 210 deg. is reached, the inertia of this column is largely taken up, and the rate of increase of pressure starts to fall off. At 250 deg. the discharge part is reached. Now, the water finding an opening to the lower pressures behind the blade, rushes by it, dropping the pressure rapidly to 270 deg. At this position the following blade picks up the load and carries it upward until the hole is covered at 300 deg.

From these indications it seems that the hammer was produced as the blades picked up the discharge pressure of the foregoing blade. Such an effect, if strong enough to produce a hammer, should show on the suction card as an abrupt increase of pressure.

Fig. 23 shows the suction cards. There is only a slight indication of such an increase. At 250 deg., the point of maximum volume between blades, the suction pressure is a minimum. From there it builds up at a very moderate rate to the practically constant level of suction maintained throughout the rest of the card.

It must be remembered in analyzing this suction card that, as the pressure is dropped through to the next blade, the suction side may move away from the resulting pressure wave with sufficient speed to prevent a registration of this effect upon the indicator. If this is true, the only possibility of catching this effect upon the blade is to decrease the hammer and note the difference in the resulting curves. This is done in the curves shown in Figs. 24 and 25.

To decrease the hammering several methods were possible. The water column could be dropped more gradually through varied port shapes. Also, pressure between blades could be built up to the discharge pressure through varied discharge-port positions or through varied suction-port positions. This latter method was the one adopted.

It was reasoned that since the pump was drawing such a high vacuum with the suctions as arranged, the hammer effect, which seemed to be a cavitation at maximum displacement volume, and the losses due to slip, could be reduced considerably if the suction port was opened farther along the blade path. This would result in the maximum volume between blades being more

nearly filled, and in the pressure at the point of release being higher. Therefore, and to make some allowance for the evident effects of inertia of the water, the suction port was drained down to 120 deg. from top dead center.

With this port position the usual run was made and the results plotted as the *A* curves of Fig. 21. Many important changes are to be found under the new condition.

First, in spite of the fact that the suction port is open approximately 5 deg. after the discharge is opened, there is very little

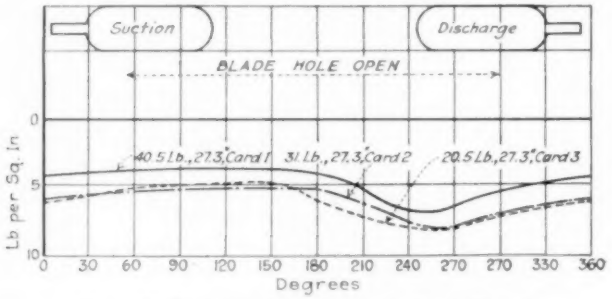

FIG. 23 SUCTION DIAGRAM FOR RUN NO. 5

tendency for the load to slip at the higher discharge pressures. This also indicates a complete occupation of the displacement volume before discharge, as one should expect with an open suction to that point.

Second, the water horsepower does not exhibit such a marked tendency to fall off at the higher loads. This is, of course, a direct result of the maintenance of the head capacity.

Third, the volumetric efficiency again shows the gain with an increase at the same heads of approximately 6 per cent.

Fourth, the overall efficiency exhibits two desirable characteristics. To start, the maximum efficiency is $2^1/_2$ per cent higher than the maximum efficiency of the previous run. It also maintains a high efficiency over a greater range. The difference lies largely in the fact that no additional losses are encountered at high pressures as were before.

Obviously, this port arrangement is superior to the original, and it seems to be because the space between the blades is fully charged with water as it is opened to the discharge. The indicator diagrams for this run (Figs. 24 and 25) check the theory.

The most noticeable feature of the first part of the pressure curve is the slight decrease of suction at low heads. The high heads seem to retain the same amount as before. Next it will be noticed that the high-pressure curves reach their maximums nearly 30 deg. before discharge. Not only does this indicate a full load of water between blades, but it shows that the pressure between the blades when relieved to discharge has been increased. It will be noted that the hammer effects are considerably less in this run, probably due to this result. Further, the drop in pressure between blade impulses is considerably decreased by this decreased discharge pressure.

If this blade displacement at discharge is more nearly full of water, and if the hammer is the cavitation between these blades, then the dip in the suction curve should be somewhat removed by the improved conditions. This we find to be the case. Also there is less tendency to draw vacuum as the blade swings by the suction port. This, while an advantage in its milder form, may become one of the limitations upon the continuation of improvement by the adjustment of the suction port.

There is another limitation to the increase of efficiencies possible by this port displacement in the slip of the water past the blades. Obviously, if the suction port is lowered too far along the periphery of the casing, the inertia of the water will no longer sustain the discharge pressure as the suction closes, but will allow some back flow into the suction line. The point at which the maximum discharge will be obtained is the point just before this back flow occurs, and will vary with the pressure and the speed of the pump. A location of this point can be made only by tests under the normal operating conditions.

CONCLUSION

In considering the last tests the conditions must be kept in mind. First, the tests were run at a speed considerably lower than those recommended for the pump. Second, conditions were maintained which were most detrimental to its operation. As a result, certain limitations must be placed upon the conclusions drawn from these discussions and the results must be taken to serve more as an indication of probable results than as an indication of the performance to be expected.

For instance, the performance of the pump when running under conditions which do not provoke hammering might not be im-

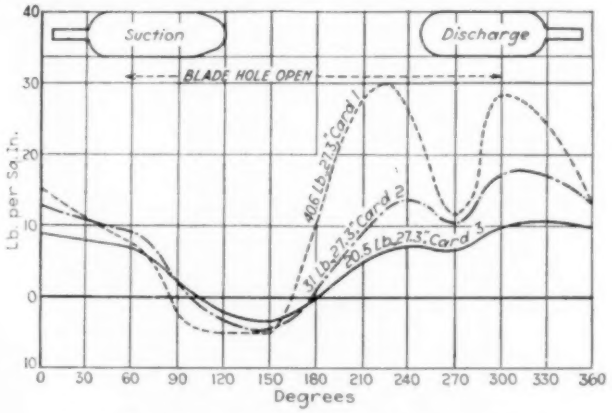

FIG. 24 PRESSURE DIAGRAM FOR RUN NO. 6

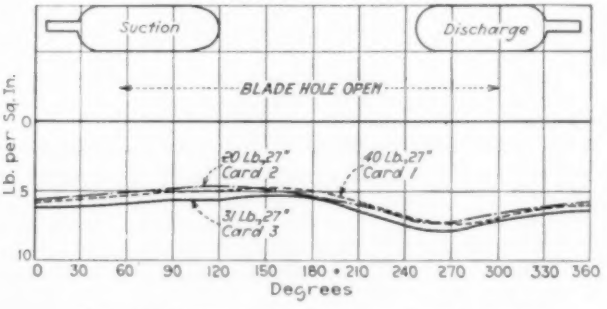

FIG. 25 SUCTION DIAGRAM FOR RUN NO. 6

proved by the port adjustment which showed so well in this test. On the other hand, if running at rated speed, 400 r.p.m., a movement of the port to even greater extremes might prove beneficial. These variations and many others are left undetermined due to the lack of time and the lack of equipment necessary for such an investigation.

Similarly, the problem of utilizing the inner pump, either as a booster or as an auxiliary, has not been touched nor has the effect of supporting the outer end of the rotor. In all these questions this paper must serve merely as a foundation for detailed work which may follow even as it has served as a foundation for the first step of the detailed solution of the hammer effect.

HYD-51-13

Mechanical Vibrations in Penstocks of Hydraulic Turbine Installations

By J. P. DEN HARTOG,[1] EAST PITTSBURGH, PA.

In this paper the author presents a theory showing that objectionable vibration phenomena are to be expected in the penstocks of Francis turbine installations when the number of buckets on the turbine runner is one less than the number of guide vanes, and that satisfactory operation should be obtained when this relation is avoided. Observations on eight different installations show good agreement with the theory.

IN THE penstocks and power houses of Francis turbine installations undesirable vibration phenomena have been observed from time to time which are known to be due to the play of the water on the buckets of the revolving runner. The subject was investigated by Mr. Roy Wilkins a number of years ago, and details of his work were published in Trans. A.I.E.E., 1923, pp. 1001, et seq. The frequency of the vibration was found by him to be the product of the revolutions per minute and the number of runner blades, and the trouble seems to have been cured by replacing the runner by another one with a different number of blades. The reason for this was unknown. The paper of Mr. Wilkins is the only one on this subject which has come to the author's notice. Regarding the choice of the number of runner buckets, there is a definite tendency among water-wheel-building concerns to avoid making this number equal to that of the stationary guide vanes, possibly on account of unpleasant experiences.

This paper is the result of certain work done in connection with a particularly troublesome installation in one of the Southern states. The vibration in that plant was reduced to satisfactory limits by replacing the existing runner by another one with a different number of buckets. A simple theory for the phenomenon was found, which is in good agreement with observations made on six other Francis installations in that neighborhood.

Theory

Fig. 1 represents schematically the scroll case and runner of a Francis turbine. The number of runner buckets n_1 is in general different from the number of guide vanes n_2. The stream of water entering the scroll case at the section AA splits up into n_2 partial streams, each of which enters the space between two guide vanes. Fixing our attention on *one* of these partial streams, it is seen that n_1 buckets pass it per revolution, so that the number of impulses per second given to it is: $n_1 \times$ (r.p.s.).

Since these impulses are not sinusoidal, higher harmonics of this frequency will also exist in the partial stream. The impulses travel away from the point of their generation with the velocity of sound in water, and finally arrive at the section AA of the penstock.

The water in the penstock at AA therefore receives impulses of the frequency $n_1 \times$ (r.p.s.) from n_2 different partial streams, which have to be added together with their proper phase relations. Under certain conditions most of these impulses will cancel each other, while in other cases they will add up to a considerable disturbance.

An expression for the phase difference between the impulses at AA of two adjacent partial streams will now be derived.

The angle between consecutive buckets is $360°/n_1$, and the angle between guide vanes is $360°/n_2$. If bucket 1 lines up with guide vane 1 (Fig. 1), the angle between bucket 2 and guide vane 2 is:

$$\left(\frac{1}{n_2} - \frac{1}{n_1}\right) \times 360° = \frac{n_1 - n_2}{n_1 n_2} \times 360°$$

The interval between the impulses on two adjacent streams is equal to the time it takes the runner to travel through this angle, namely,

$$\frac{n_1 - n_2}{n_1 n_2} \times \frac{1}{\text{(r.p.s.)}} \text{ seconds}$$

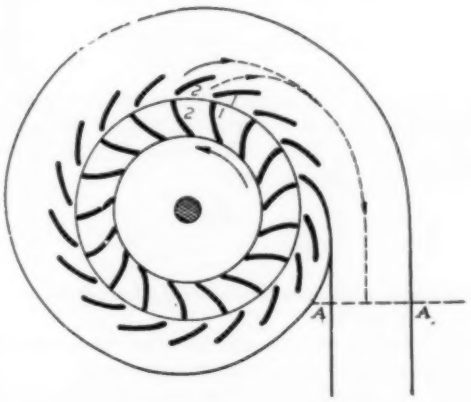

Fig. 1 Schematic Representation of Turbine Scroll Case and Runner

Let the difference in the paths of the impulses on the two streams be a feet, and the velocity of sound in water be v feet per second. It takes a/v seconds for the wave front to travel this extra distance, since the actual stream velocity of the water in the scroll case is so small as to be negligible with respect to the velocity of sound. The total time lag between two adjacent impulses at AA is therefore

$$\frac{n_1 - n_2}{n_1 n_2} \times \frac{1}{\text{(r.p.s.)}} + \frac{a}{v} \text{ seconds}$$

Since the frequency of the vibrations is $n_1 \times$ (r.p.s.), the phase difference between the impulses is found to be:

$$\frac{\varphi}{360°} = \frac{n_1 - n_2}{n_2} + \frac{n_1 a}{v} \times \text{(r.p.s.)} \quad \ldots\ldots\ldots [1]$$

In deriving this formula no definite assumption has been made regarding the path of travel of the waves from the spot of their generation to the section AA. This phenomenon is fairly complicated, consisting of many reflections against the sides, but it can be safely said that the main wave front in which we are in-

5	19	20	154	77	92	49	3	0.83
6	16	26	200	63	85	53.3	128	0.31
7	18	20	171.4	65	88	51.5	23	0.00
8	19	20	171.4	75	83	54	2	....

terested here will move along the scroll case toward the penstock. In this case we find approximately for the distance a

$$a = \frac{2\pi R}{n_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [2]$$

where R is the radius of the center line of the scroll case, which varies but slightly throughout the scroll case.

In case the phase angle φ of Equation [1] approaches 0 deg. or 360 deg., the various impulses will be in phase and the resulting disturbance in the penstock will be considerable.

The number of guide vanes or runner blades on existing Francis turbines is in the neighborhood of 18, and the diameter is about inversely proportional to the speed. Due to this the length of the center line of the scroll case is approximately equal to one wave length of the vibration in most installations, or

$$2\pi R = \frac{v}{n_1 \times (\text{r.p.s.})} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

in which the velocity of sound in the scroll case is taken to be 4500 ft. per sec. Table 1 shows the limit of accuracy within which this statement holds. Combining [1], [2], and [3], the following simple expression results:

$$\frac{\varphi}{360^\circ} = \frac{n_1 - n_2 + 1}{n_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

The phase angle φ becomes zero when the numerator $n_1 - n_2 + 1$ vanishes, or, in words:

Penstock vibration is to be expected when the number of runner buckets is one less than the number of guide vanes.

It can be also seen from [4] that in case the number of runner buckets is two less than or equal to the number of guide vanes, $\frac{\varphi}{360^\circ} = \frac{1}{n_2}$. Representing the various impulses by vectors will yield a diagram like Fig. 2, in which the resultant is zero, while in the previous case the vectors would all lie in a straight line and add up to one long resultant.

When there are one more or three less runner buckets than guide vanes the angle is $\frac{360^\circ}{2n_2}$; again giving a vector diagram like Fig. 2, with the difference that we go around the circle twice instead of once only.

The conclusions can be drawn, that for an equal number of runner buckets and guide vanes no particular penstock vibration trouble is to be expected. However, in such a construction the impulses occur on all runner buckets at the same time and the torque may become quite non-uniform. This may lead to non-uniformity of rotation, or in special cases to torsional vibrations between the generator and the turbine. The reactions of such an oscillating torque will set up vibration in the power house, but *not* in the penstock. Troubles experienced from this cause are probably responsible for the fact that the combination is avoided in recent constructions.

It is to be emphasized once more that the fundamental formula [1] as well as the conclusions deduced from it are only approximations and can represent only the principal traits of the phenomenon. The main inaccuracy lies probably in the assumption that the disturbances travel as units along the center line of the scroll case. The actual condition differs from this assumption in two ways. In the first place, there will be some damping of the waves in the scroll case, so that an impulse generated deep in the narrow end (Fig. 1) will arrive at AA with less intensity than one generated in the wide part. This will change the circular vector diagram of Fig. 2 into a spiral one like that shown in Fig. 3.

Then there will be diffusion. An instantaneous disturbance inside the penstock will not arrive at AA as an instantaneous occurrence. Also, the "main" effect will be instantaneous at AA, but after this there will be a train of disturbances which have traveled longer paths and have undergone one or more reflections against the walls. This tends to degenerate individual vectors of Figs. 2 or 3 into a "diffused vector" such as that represented by Fig. 4. The details of this process are too complicated to follow, but it is believed that the simple result [1] and the conclusions therefrom are sufficiently accurate, since observations made on several plants are in good agreement with it.

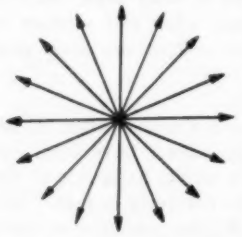

FIG. 2 VECTOR DIAGRAM OF IMPULSES WHEN NUMBER OF RUNNER BUCKETS IS TWO LESS THAN OR EQUAL TO THE NUMBER OF GUIDE VANES

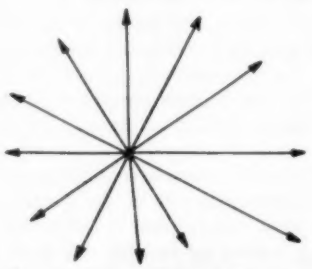

FIG. 3 SPIRAL VECTOR DIAGRAM

The vector representation can be applied only to pure sinusoidal impulses, while the actual disturbances will have higher harmonics in them. These can be considered separately and can be brought within the scope of [1] when it is considered that the second harmonics of the impulses of a runner with n_1 buckets act exactly in the same manner as the fundamental harmonics for a hypothetical runner with $2n_1$ buckets. It is found that in general these higher harmonics are of no particular importance.

FIG. 4 "DIFFUSED VECTOR" DIAGRAM

The most direct way in which to eliminate penstock vibration is of course to so design the shape of the blades as to make the individual impulses small. However, since efficiency and other considerations are of far greater importance in determining the shape of the blades, this manner of attack does not seem quite practical, especially since satisfactory operation can be secured by simply avoiding a number of buckets one less than or equal to the number of guide vanes.

EXPERIMENTAL VERIFICATION OF THEORY

The measurements of the vibration in the various hydroelectric installations tested were made by means of a simple seismic vibrograph, which was placed on the penstocks or in other suitable places near the turbine. This instrument records the vertical vibrations magnified ten times in the form of an indentation in a clear celluloid strip. A second line on the same strip carries timing marks. These records are hardly visible with the naked eye, but can be conveniently magnified. On the job we use for this purpose a hand microscope of 30 diameters magnification which is carried with the instrument and makes

it possible to immediately inspect the record, the total magnification thus being 300 times. A scale inside the microscope also shows the absolute magnitude of the amplitude of the vibration. This is more convenient than an oscillograph because the record can be immediately examined and another made in case it is not satisfactory. Later, at the office, the celluloid strips can be microscopically photographed at practically any magnification;

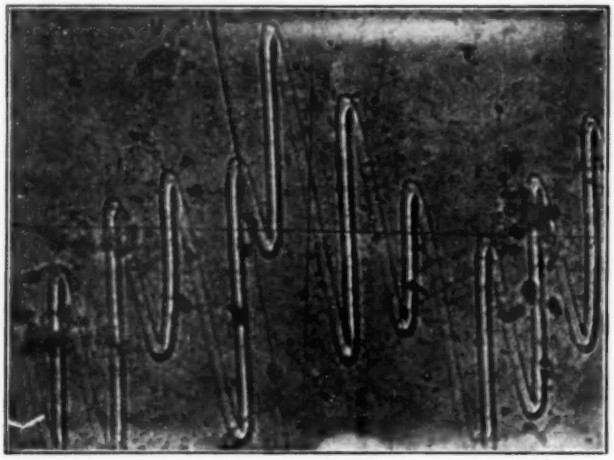

FIG. 5 VIBROGRAPH RECORD SHOWING VERTICAL VIBRATION OF PENSTOCK OF A TROUBLESOME TURBINE

the thickness of the line being the only limitation. Fig. 5 shows such a record of the vertical vibration made on the penstock of a troublesome turbine (No. 5 of the Table 1); Fig. 6 is a similar record on the penstock of a turbine with but little vibration (No. 4).

FIG. 6 VIBROGRAPH RECORD OF PENSTOCK OF A TURBINE OPERATING WITH BUT LITTLE VIBRATION

The results of the investigation on eight Francis turbines are shown in Table 1, to which the following remarks apply. Turbines Nos. 1 and 2 are the same installation with different runners. In fact, this particular station gave rise to the whole investigation, because the vibration was considered dangerously large. As a result of the analysis described in the paper, the original 17-vane runner was replaced by a 16-vane one of the same diameter and having the same clearances, which led to a decided improvement in operation. This improvement is not so apparent from the reading on the penstock itself; however, the vibration of the concrete inside the power house near the penstock entrance was reduced from 2.40 mils to 0.20 mil.

Turbines Nos. 1, 2, 3, and 4 are directly comparable because they operate under approximately the same head (600 ft.) and the penstocks are open, i.e., not buried in concrete.

Turbines Nos. 5, 6, 7, and 8 operate under a lower head (200 ft. approximately); Nos. 5 and 6 have open penstocks, No. 7 has the penstocks partly concreted in, while No. 8 has them completely concreted in. Therefore no measurement could be made on the penstocks of No. 8, but the vibration could be found on the concrete structure at the headgates and even as far as the top of the middle of the dam.

The frequency of the vibration was in all cases proportional to the product of the number of revolutions and the number of runner buckets, regardless of the difference between n_1 and n_2. This is not so clear from the records which Mr. Wilkins obtained.

In general, the observations have so far been in fair agreement with the theory. The author has had no opportunity to check an installation with the same number of buckets and vanes. It would be of considerable interest to know the nature of the trouble experienced in such cases.

ACKNOWLEDGMENT

The author wishes to express his indebtedness to the engineers of the Aluminum Co. of America, particularly Mr. J. P. Growdon, for their valuable help and cooperation.

Discussion

R. WILKINS.[2] In addition to the paper in the *Transactions* of the A.I.E.E. to which reference has been made, there was published by a subcommittee of the N.E.L.A. Hydraulic Committee of 1925–26 a report on vibration in which Fig. 7 was included.

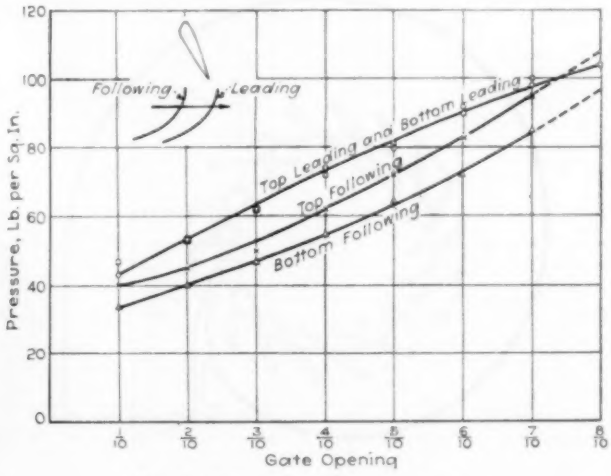

FIG. 7 PRESSURE AT RUNNER INLET
(Using explorer pipe in runner filled with air to minimize leakage and to eliminate centrifugal action.)

The values plotted are for a 40,000-hp. Francis-type turbine wherein the difference in pressure as plotted represents a considerable portion of the total head on the units. This is the fundamental reason for the resulting vibration, and in practice was partly cured by cutting off some two inches of the outer edge of the runner blades, thereby giving more clearance and a better chance for the pressure values to equalize. Contrary to expectations, this raised the efficiency of the unit. As stated in the paper, the runner was later replaced by one having a different number of vanes with still more improvement.

High-pressure differences across the face of the runner opening are due to design and are frequently encountered where the physical dimensions are reduced in order to save cost. Juggling runner and guide-vane combinations is only an expedient, not a cure, since a cure requires the removal of the cause.

A great deal of disagreeable, though not often dangerous,

[2] Consulting Engineer, Pacific Electric Mfg. Co., San Francisco, Cal.

vibration comes from draft-tube action, and this is far harder to remedy. The so-called breathing of the penstock can usually be traced to the draft tube, where the pulsations may be as slow as one per second.

One of the most difficult cases to analyze that has come to attention was caused by the balance chambers in a runner wherein, when the wearing rings wore down, the clearance was about the same as the leakage clearance. This gave an intermittent action with some 0.03 in. side motion on the turbine shaft. Replacing the wearing rings cured this trouble completely.

It is not usually sufficient to study vibration alone when hydraulic "trouble shooting;" pressure variations from various places also are desirable. Any one of several types of equipment is available, though modern oscillographs with the commercial carbon-pile telemeters form the most flexible arrangement for visual use and allow a permanent record being taken wherever desirable.

A. V. KARPOV.[3] The theory developed in the paper has a much wider application and is of much more importance than is modestly admitted by the author. The case referred to in the paper, where the disturbance that produces the vibration was due to the shape of the guiding vanes, represents only one of the many possible cases.

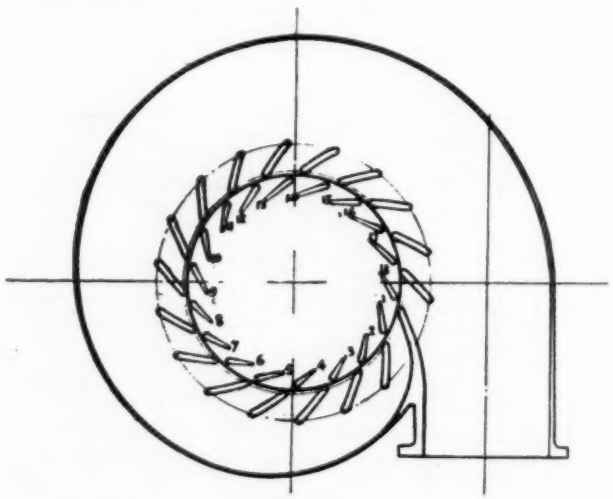

FIG. 8

Any kind of disturbances that are regularly occurring at the runner blades can accumulate and give a resultant heavy vibration either at the penstock or in the scroll case of the turbine. For instance, cavitation disturbances at the runner can produce similar vibrations in the penstock and would be subject to the same theory. It is of importance to keep that in mind, in order to avoid the possible mistake of attributing vibrations similar to that described by the author to a similar cause.

If the vibration is due to the shape of the guiding vanes, then a simple changing of the number of runner buckets will be a sufficient cure for all troubles. If the vibrations are due to cavitation disturbances, then a change in the number of runner buckets along the lines suggested by the author will eliminate the vibration, but the turbine will still be unsatisfactory due to cavitation and resulting pitting, and the fundamental cure of the troubles would be rather in eliminating the cavitation than in the simple change of the number of runner vanes.

Another interesting problem in connection with the theory developed by the author is the influence of the damping. The author mentioned the damping and the diffusion as some of the causes that would result in a difference between the figured and measured values, but does not attempt to evaluate the influence of these factors, which in some cases may be important enough to modify the conclusions.

An attempt was made to evaluate the comparative amplitudes of penstock vibrations, applying the author's theory, but taking into account the disturbing effects of damping and diffusion. The turbine mentioned in the paper under Nos. 1 and 2, with 18 guide vanes and 450 r.p.m., was investigated, and the comparative amplitudes of vibrations of the water column of the

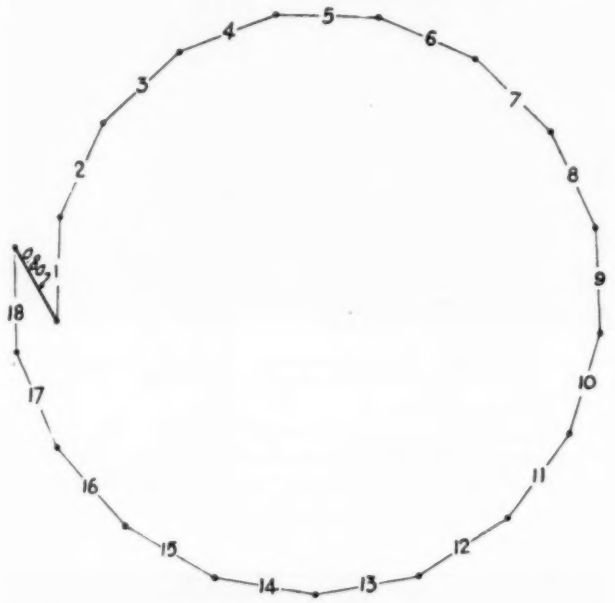

FIG. 9

scroll case and penstock were evaluated for runners with different numbers of buckets.

A graphical method was chosen, and a number of vector diagrams were drawn. In these diagrams it was assumed that a disturbance of the amplitude equal to unity was produced every time when the edge of the runner vane was passing the edge of a guiding vane.

Two sets of vector diagrams were drawn, one disregarding the damping and the other one considering the damping.

The first set of diagrams was drawn, starting with the guide vane shown as 1 on Fig. 8; the path that the disturbance has to travel until it reaches the center line of the scroll case and meets the disturbance coming from guide vane 2 was scaled and the time figured assuming the velocity of propagation of the disturbance of 4700 ft. per sec. The lag in time between the first and second impulses was figured, the path and the time necessary for the second disturbance to meet the first one was determined, and assuming sinusoidal impulses the vector of the second impulse was added to the vector of the first impulse with the proper phase angle; to this resultant vector the vector of the third impulse was added with its proper phase angle, and so on.

In these diagrams the connecting line between the starting point and any of the points of the diagram will represent the amplitude of the vibrations at the corresponding point of the scroll case, and the closing line of the diagram from starting point to the end of the vector 18 will represent the amplitude of the vibrations at the penstock. The values obtained in this

[3] Designing Engineer, Hydraulic Department, Aluminum Company of America, Pittsburgh, Pa.

way correspond to the values that were figured by the author analytically.

Figs. 9, 10, and 11 show such vector diagrams for 16-, 17-, and 19-bucket runners.

The second set of diagrams was drawn in the same way, but the damping and diffusion were taken care of, reducing by a certain amount the size of every resultant vector.

Figs. 12, 13, and 14 show such vector diagrams for the same turbine and for 16-, 17-, and 19-bucket runners in which every resultant vector was reduced by 10 per cent, which would mean that between every two impulses a 10 per cent dissipation of the vibration energy took part.

Referring to these figures, the conclusion that can be drawn from the diagrams is that, regarding or disregarding the damping and diffusion, the largest amplitude of vibrations will occur at the penstock for a 17-bucket runner.

Regarding the best possible combination with reference to the smallest vibration amplitude at the penstock, the 16-bucket runner will give the best result, if the damping is disregarded; and if the damping is considered, the best result will be obtained by using a 19-bucket runner. In contrast with the 17-bucket runner, in the 16- and 19-bucket runners the maximum amplitude of vibration will occur in the scroll case, but not in the penstock. For a 16-bucket runner, the maximum vibration that occurs in the scroll case is larger than for a 19-bucket runner. A still more interesting conclusion that can be drawn from this diagram is that the damping and diffusion decrease the vibration amplitude at the penstock for a 17- and 19-bucket runner, but considerably increase it for a 16-bucket runner.

Some time after these investigations were made, the field measurements which the author made on this turbine with 16-, 17-, and 19-bucket runners gave an exceptional opportunity to compare the theoretical and actual values.

Fig. 10

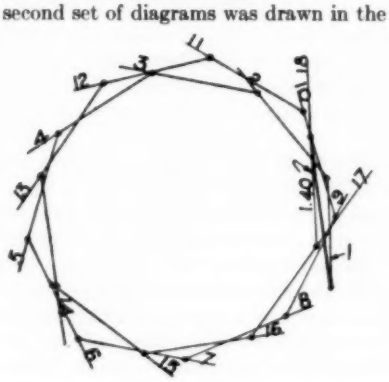

Fig. 11

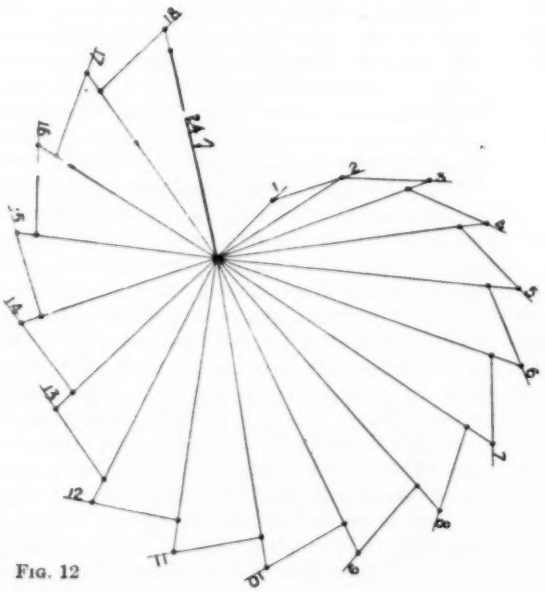

Fig. 12

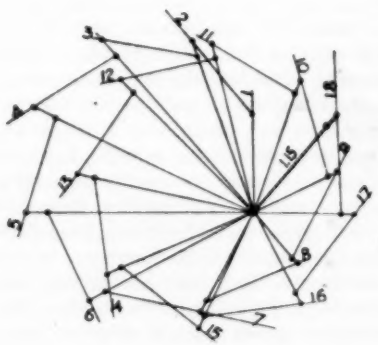

Fig. 14

Fig. 13

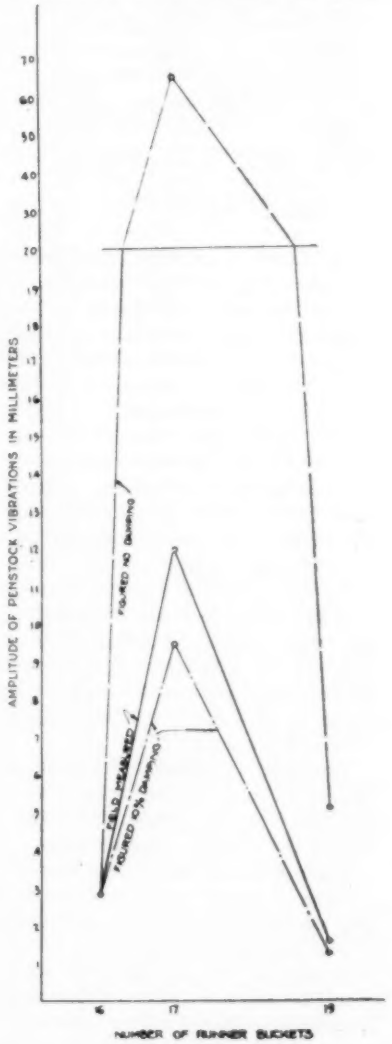

Fig. 15

In order to make such a check, the amplitudes of vibration at the penstock scaled on each set of diagrams were multiplied by a coefficient so as to have the amplitude of the vibrations of the 16-bucket runner equal to 29 mil., the value that was obtained by actual measurement.

Table 2 shows the measured and the theoretical values.

TABLE 2 AMPLITUDES OF VIBRATIONS AT THE PENSTOCK

Number of runner buckets	16	17	19
Double vibration amplitude measured at the penstock in the valve house, expressed in millimeters	0.29	1.20	0.16
Vibration amplitudes at the penstock scaled on the diagrams, disregarding damping	0.80	17.90	1.40
The same vibration amplitudes expressed in millimeters (coefficient, 0.362)	0.29	6.48	0.51
Vibration amplitudes as scaled on the diagrams, assuming 10 per cent damping between impulses	2.4	7.8	1.15
The same vibration amplitudes in millimeters (coefficient, 0.121)	0.29	0.95	0.14

The values of deflection in millimeters for the three conditions —no damping, actually measured, and 10 per cent damping between impulses—are shown on the diagram, Fig. 15. The amplitudes figured from diagrams disregarding damping and the measured amplitudes are so different for a 17-bucket runner that it was necessary to change the vertical scale of the diagram to keep it to a reasonable size.

The results figured for 10 per cent damping are amazingly close to the ones actually measured.

A further study of runners with a number of buckets larger than 19 or smaller than 16 did show that the amplitudes of vibrations at the penstock as well as the maximum amplitudes are decreasing rapidly.

For this particular kind of turbine, it can be stated that the combination of 18 guide vanes and 17 runner vanes represents the worst possible combinations so far as the vibration amplitudes in the scroll case and penstock are concerned. A 16-bucket runner represents a decisive improvement. A 19-bucket runner is still a better combination and is practically as good as a 15-bucket runner.

The general statement that was made in the paper, that a number of runner vanes equal to the number of guiding vanes less one is a bad combination, could be modified by stating that, if the number of runner vanes is to be close to the number of guiding vanes, then for the kind of turbines investigated the number of runner vanes equal to the number of guiding vanes plus one represents the best combination.

The investigation carried out for the turbines can be applied to pumps as well, but since the sense of revolution of a pump would be opposite to that of the turbines, for a pump of similar design the number of runner vanes equal to the number of guiding vanes plus one will represent the combination that ought to be avoided.

The amplitude of vibrations measured at the concrete floor of the power house does not show such a striking agreement with the theoretical values. Quite a number of additional factors involving the concrete structure enter which probably change the situation considerably.

One point that is of the utmost importance with all vibration studies is to be emphasized. The theory brought up by the author and all conclusions based on this theory are of practical importance as long as the vibration frequencies imposed on the structure are out of harmony with the natural frequencies of the whole structure or a part of it.

By changing the number of runner blades, the vibration frequencies will change, and if the new frequencies harmonize with some of the natural frequencies, then, although the original trouble is eliminated, some new disturbances may appear. Since the evaluation of the natural frequencies of vibration is a rather complicated procedure and in many cases it is impossible to obtain reliable figures, the making of a recommendation that involves a change of frequencies of vibration involves a certain gambler's chance that sometimes has to be taken.

It is impossible to refrain from admiration of the simplicity and usefulness of the theory established by the author, which cleared up the problem that used to be so very obscure.

LEWIS F. MOODY.[4] The author has pointed out some considerations affecting vibration of turbines, penstocks, and surrounding structures which are not believed to have heretofore occurred to those investigating such problems. His method of analysis is interesting and ingenious, and gives another factor to take into account in handling vibration problems.

Fortunately serious mechanical vibration, of a character which either endangers the life of structures or involves actual operating difficulties or seriously objectionable noise, is a rather rare phenomenon among the great number of hydraulic power installations extant; and consequently many of those working in the hydraulic field, including the writer, have had no occasion or opportunity to take up the problem actively. When serious vibration does occur, however, it may indeed be serious, so much so that it may be considered inadvisable to operate a unit at all until the condition is cured. It may therefore be well for those who have not been faced with the problem as a question of cure to give it due study as a matter of prevention.

It is the feeling of the writer that the most important consideration is that of eliminating or at least minimizing the initiation of vibrations at their source. This is a matter of design of guide vanes, runner vanes, their interaction, and the form of transition space between them. The author, however, seems to view this possibility with some pessimism, for he says: "since efficiency and other considerations are of far greater importance in determining the shape of the blades, this manner of attack does not seem quite practical. . . ." There are probably cases where vibration is of such serious consequence that efficiency and other considerations become relatively of minor importance instead of "far greater importance;" but the point which the writer wishes particularly to bring out is that the author seems to imply some incompatibility between smooth operation and efficiency. The writer's view is that the same design factors which lead to avoidance of vibration are also necessary for high efficiency.

If the water can be conducted through the guide vanes and then formed into an integral, uniformly moving ring of fluid before entering the runner, steady conditions of entrance will be assured. Breaking the flow up into separate jets with decided velocity variations around the circumference will be conducive to vibration, and particularly a design which permits the formation of voids or cavities in the flow between successive jets. In pronounced cases of vibration the writer should suspect the presence of such voids or cavities, since any such void, becoming filled with vapor instead of water, immediately becomes a source of pressure waves or water hammer. In cases of severe vibration it would seem likely that another undesirable accompaniment would be pitting. The writer should like to ask the author whether the severe cases of vibration which he reports showed any indications of pitting.

The author's analysis is directed to the vibration caused by pressure waves traveling through the water in the turbine casing toward the penstock. He also mentions the vibrations which travel directly into the metal structure of the turbine and then

[4] Consulting Engineer, Cramp Morris Industrials, Inc., Philadelphia, Pa. Mem. A.S.M.E.

into the foundations. His ingenious theory for the pressure-wave phenomon results in the conclusion that "vibration is to be expected" when there is one less runner vane than the number of guide vanes. The second kind of vibration just mentioned would of course be most intense when the runner and guide vanes are equal in number.

That it is possible to design runner vanes, guide vanes, and transition space so as to avoid vibration (and without sacrifice of efficiency), irrespective of the numbers of vanes used, would seem to be borne out by the records. The writer has hastily reviewed the statistics of I. P. Morris turbines, and while the great majority of the installations do not exemplify the unfavorable vane numbers, he finds that 31 units, aggregating about 860,000 hp., embody the author's condition of "expected vibration;" namely, number of runner vanes one less than number of guide vanes. He also finds one case of numbers of guide and runner vanes equal. In not one of these installations has any vibration been reported. Naturally some amount of vibration must exist in any moving machinery; but this incidental vibration is not what is meant by either the writer, or, it is believed, by the author of the paper.

As a matter of detail, it would appear to the writer from a rough calculation that the approximate formula [3] in the paper would be substantially correct for heads of around 600 ft., but for heads of 200 ft. or lower, the first member of the equation would not be much more than one-half the second member, for usual turbine proportions. In such cases, therefore, the relation derived would be modified to give a difference between n_2 and n_1 of one-half instead of one; so that the use of $n_2 - n_1 = 1$ might be sufficiently remote from the condition of exact synchronism of arrival of pressure waves at the penstock to avoid actual trouble.

It is hoped that the author may continue his studies in this field, and it is believed that he has given a useful method of attack and has pointed out some interesting considerations.

GEORGE A. JESSOP.[5] The author has offered a most interesting paper, with an admirably presented theory, explaining the cause of a certain type of vibration which has, in a few instances, caused trouble in the operation of hydraulic turbine installations and which is apparently present, to some extent, in all high-head plants. The investigations were made very carefully and thoroughly, and the gathering of data at other plants to check the theory is a particularly valuable feature.

Vibrations of hydraulic turbine installations may be classified in two groups. The first group will include the type of high-frequency vibration described by the author. The second group will include vibration caused by disturbances in the flow, the most frequently encountered instances being caused by the draft tube. In general, these vibrations are of low frequency. It is only the first group that will be discussed.

It is of interest to note that the turbines investigated by the author were all of a comparatively low-speed type, the specific speed being in each case 50 or less. Usually the types of turbine made to cover this range of specific speed are designed in such a manner that the gates are closer to the buckets than for the higher specific speed Francis runners. Since low specific speed runners are generally used under heads higher than 150 ft., the r.p.m. and the peripheral velocity are high, the number of buckets is usually greater than for low specific speed turbines, and, therefore, there are a larger number of buckets passing a given gate per second. If vibrations are set up, they are of high frequency. It is necessary to keep such vibrations at a very low amplitude in order to have entirely satisfactory operation.

[5] Chief Engineer, S. Morgan Smith Co., York, Pa.

Installation No. 1 of Table 1, where the primary investigation was made, has a turbine with a specific speed of about 26 and the normal head is 630 ft. The power house contains two units, without provision for any additional units in the future, and therefore has less mass than the usual power house with three or more units. The draft tubes are essentially of the vertical type discharging into large tail pits, each pit having openings on two sides, thus necessarily still further reducing the foundation supports. The penstock consists of pipe line and tunnel, with a large surge tank about 1000 ft. from the power house. The pipe line between the surge tank and the power house and for several hundred feet upstream from the surge tank to the first tunnel is not buried in concrete or earth, except for a short distance at and near the power house. Much of the pipe between the surge tank and the power house is supported on high bents affording little resistance to vibration. The turbines themselves are free from troublesome vibration.

Plant No. 5, which shows a vibration amplitude greater than that of plant No. 1, also has an exposed pipe line. Plant No. 8, which has been in satisfactory operation for about ten years, is a four-unit power house, with the supply pipe entirely buried. Both of these plants have turbines with the number of buckets one less than the number of gates; that is, $n_2 - n_1 = 1$, the combination found to be undesirable for plant No. 1.

For practical reasons, various bucket and gate combinations have been used by hydraulic-turbine manufacturers. There are many plants with $n_2 - n_1 = 1$, but as far as is known to the writer the only two having this bucket and gate combination which have had sufficient vibration to cause an investigation are the one discussed by Mr. Wilkins in the *Transactions* of the A.I.E.E., 1923, and referred to by the author, and the plant on which the present primary investigation was made. It is of interest to note that there has recently been installed a turbine having a 17-bucket runner and an 18-gate case on the same system where the trouble was experienced leading to Mr. Wilkins' investigation. This company was very insistent that the later installation be free from vibration, and, having been forewarned, both manufacturer and purchaser were particularly careful to be certain that this trouble should not develop. The installation has now been operating in an entirely satisfactory manner for several years and is reported to be absolutely free from vibration troubles of any kind. It is only a two-unit plant, but with elbow draft tubes which permit a rigid foundational support. The penstock is long and strongly supported where it is not entirely buried.

There are a fairly large number of installations having the same number of buckets and gates. In the writer's personal experience there is only one of these units which is reported to be operating in a manner that is not entirely satisfactory. This particular installation has been in service nearly ten years, but recent reports indicate that there may be vibration of the turbine itself. This would tend to support the author's theory that an equal number of buckets and gates have a bad effect on the turbine, but not on the pipe line.

Another installation not in the writer's personal experience, but concerning which he has received authentic reports, had the same number of buckets and gates and there was troublesome vibration both on the turbines and pipe line. A new runner was installed having the number of buckets one more than the number of gates, with very good results. Later it was desired to increase the horsepower somewhat, and to do this a runner was used having the number of buckets one less than the number of gates. Troublesome vibration in the pipe line did not occur, although the pipe is exposed.

A large number of high-head installations have been made with the number of buckets one more than the number of gates,

and, in agreement with the author's theory, without vibration trouble developing.

A very large number of plants operating under heads of 100 ft. and less are in service, with turbines having $n_2 - n_1 = 1$. These power houses are of various degrees of massiveness and rigidity, and at least some of them have exposed penstocks. Of the hundreds of installations of this kind with which the writer has been connected, there is not one where vibration of the type under discussion is known to be taking place.

The author's investigation and the experience of the art show that, where heavy power houses and buried pipe lines are used, this type of vibration has not been of sufficient amplitude to be troublesome—at least to the extent of suggesting investigation or of requiring alterations. The paper suggests to the engineer and designer the possibility of making power houses lighter and with less foundational support than has been the custom in the past. It is believed that the saving which can thus be effected is not a sufficiently large proportion of the total expense of the installation to justify the assumption of any risk. Therefore, before advocating the decreasing of the mass of the power house and using lighter foundations, with greater spacing for pipe-line supports, it would seem that the problems involved should be more fundamentally explored, as has been elsewhere recommended by the author. Hydraulic-turbine design and engineering have advanced to the extent that entirely satisfactory Francis turbines can be built without using the gate and bucket combinations that have been found undesirable according to this paper, and this can be done without adding any new limitations of head, horsepower, speed, and efficiency.

The author has made a valuable contribution to the knowledge of the performance of hydraulic turbines.

ARNOLD PFAU.[6] The author deserves high commendation for his attempt to mathematically explain these troublesome phenomena.

There is general belief in the saying that there is no rule without exception, although the writer is convinced that the apparent "exceptions" are not real exceptions to the immutable laws of nature involved, but are rather due to incomplete knowledge of some laws of nature involved in the problem. This may to some extent justify or explain the statements made by some that the rule laid down by the author does not always prove to be correct and that, in fact, many turbines are operating without vibration, although $n_2 - n_1 = 1$.

Undoubtedly other factors, not cited in the paper, also have an effect upon the results. The writer remembers particularly an experience back in 1907 when he had the pleasure of starting the 10,000-hp. horizontal-shaft, single-discharge Francis turbine at the Centerville Plant of the California Gas and Electric Corporation, now the Pacific Gas and Electric Company of San Francisco.

That turbine was a pioneer in the application of a reaction turbine to a head as high as 580 ft., and naturally offered a number of interesting problems, or "nuts to crack."

Operating one morning at fixed-gate opening (governor blocked), the writer noticed a periodic "hum" and a corresponding swing on the pressure gage located on top of the spiral casing. This swing amounted to as much as $2^1/_2$ to 3 lb. per sq. in., or 1 to $1^1/_4$ per cent of the operating penstock pressure. Since there was no fluctuation in the head or tailwater levels, it was concluded that the cause must come from an outside source and not from within the turbine. The swing was around 43 and 44 per minute, which could not be harmonized with the speed of 450 r.p.m., or the number of guide vanes (24) or runner vanes (21).

Luckily, the operator happened to make the statement that they were pulling a heavy load at the Oakland Plant. This gave a clue, and upon further inquiry, it was learned that, due to a breakdown of one of the hydro plants of the system, their gas engine units at Oakland were pulling a heavy overload. The speed of those engines, if it is remembered correctly, was 87, and they being of the two-cycle type, it at once appeared that the 43 to 44 swings per minute were identical with the cycle of the gas engines.

It is said that the engines have since been removed from the system. Evidently on account of their lack of sufficient flywheel effect, they periodically accelerated the speed of the entire system at the beginning of the cycle, and caused a dying down of it to the end of the cycle. The turbine, operating in parallel, was naturally subjected to this swing. In other words, a periodic, relative motion existed between the rotation of the runner and the guide vanes, and since the guide vanes were set for a constant opening, the discharge through these openings was affected accordingly, causing a periodic change of velocity in the penstock which resulted in the pressure variation observed on the gage. The interpretation of the phenomena proved to be correct, in that these variations immediately stopped when the gas engines were shut down.

This experience goes to show that many factors are involved in the problem under discussion. The author has made a successful beginning of theoretical analysis, and it is to be hoped that the problem can be properly analyzed as facts are added from field experience.

BLAKE VAN LEER.[7] One of the chief functions of The American Society of Mechanical Engineers is the dissemination of new and interesting information on technical subjects. This function the paper aids in an interesting, concise manner. Wherever there is trouble with mechanical installations, there is a tendency to suppress this information or to minimize it. Such a procedure may have some temporary commercial advantages to the particular manufacturer of the equipment which causes the trouble. However, it is better to face these difficulties and problems, many of which may be insurmountable or may merely be "the fortunes of war," which any one might encounter, and to freely and frankly discuss them in an open forum of technical men, than to permit a whispering campaign to go on which frequently grossly exaggerates the difficulties and their causes.

It is presumed that the author, in order to avoid any semblance of criticism of any manufacturer or group of engineers, omitted from Table 1 the name and location of the specific installations in which vibrations were studied. This, of course, is not a serious loss, because any engineer intimately interested could no doubt secure this information from the author. In the light of this, the writer wishes to commend the Hydraulic Division, the A.S.M.E., and the author for presentation of this interesting and thought-provoking paper.

D. J. MCCORMICK.[8] The author is to be commended for his fine paper which brings up a subject of timely interest. It is evident that he has obtained some valuable field data on the subject of mechanical vibrations of hydraulic-turbine installations, but since it was impossible for him to obtain data covering all combinations of number of runner vanes as compared to the number of gates used in turbine practice, the theory which he

[6] Consulting Engineer, Allis-Chalmers Mfg. Co., Milwaukee, Wis. Mem. A.S.M.E.

[7] Assistant Secretary, American Engineering Council, Washington, D. C. Mem. A.S.M.E.

[8] Sales Manager, S. Morgan Smith Company, York, Pa. Mem. A.S.M.E.

has applied to the data he obtained and his conclusions may be at variance from the real facts.

For example, the writer's experience has been that a runner with 16 vanes installed in a horizontal cast-iron spiral-casing turbine having 16 gates showed very serious vibration at the turbine and in the penstock. The penstock was exposed, and wires were strung both at the penstock and at the turbine to obtain the frequency of the vibrations which corresponded with the number of runner vanes, or number of gates, times the r.p.m. When a runner having 17 vanes was installed in this same casing with the 16 gates, the vibration at the turbine and in the penstock was entirely eliminated. However, this runner with 17 vanes did not show as much power as a runner with only 16 vanes. A 15-vane runner was then installed in this case with 16 gates, and there was no more vibration than with the 17-vane runner, either at the turbine or in the penstock. According to the author's theory, this 15-vane runner installed in the case with 16 gates should show very serious vibration in the penstock, but in reality it does not. Manifestly there is something wrong in his theory.

Referring to Fig. 1 of this paper, it is very doubtful whether the vibrations follow along the nice flow lines which the author has indicated. Undoubtedly, the vibrations skip across the casing and possibly right across through the runner in order to take the shortest course. This may account for the exceptions to his theory which will arise, the same as the case cited. A great deal of additional field data will be necessary in order to check up and prove out any theory which is proposed to apply for all cases of this nature.

There are a large number of turbine installations in this country and in Canada having 18 gates and 17 runner vanes. This combination has been very frequently used. However, nearly all of the large vertical installations have had the penstocks well anchored and a very substantial foundation provided for the power house so that any vibrations set up were dampened out to the extent that no serious damage would ever be expected.

In quite a few of these power houses some vibration may be found at some point in the power house, and it is the exception rather than the rule to find a power house that is entirely free of such vibration.

The question has been raised as to whether the vibration in the penstock set up by a certain combination of runner vanes and gates will cause any damage in the future due to crystallization. The writer would cite an installation made in California of two 8-ft. diameter exposed penstocks made of $^{5}/_{16}$-in. at plate the upper end where they are under a head of about 75 ft. These penstocks are vibrating sidewise from $^{1}/_{8}$ to $^{1}/_{4}$ in., depending upon the load carried. They have been operating for nine years and are still in good shape.

The high-frequency vibrations set up in penstocks due to such a combination as the author cites are not nearly of the same amplitude as the one given. They are only 0.01 of 1 in., as compared to the foregoing amplitude of $^{1}/_{8}$ to $^{1}/_{4}$ in. It is to be seen that the stresses set up in the pipe are correspondingly less, so that it is very doubtful, in the writer's opinion, whether any serious trouble should be expected in the future from such vibrations, even though they are of high frequency.

It is to be hoped that the hydraulic engineers will take an active interest in this subject and work out some method of locating penstock piers and anchorages in order to dampen out the vibrations which may be set up.

Lyle A. Whitsit.[9] The author presents valuable results of a research in hydraulic-turbine operation and an effective method of analysis that should be useful to turbine designers and manufacturers. He brings out the adaptability of methods commonly used in electrical problems, that also are serviceable in hydraulic problems.

The author indicates that, where the number of runner buckets is one less than the number of guide vanes, vibration may be expected, and in general that less trouble is to be expected if the relation of buckets to vanes is any other than this. However, among the latter there are instances where excessive vibration exists. The writer knows of one case possessing the favorable relation of 17 runner buckets to 16 guide vanes where there is vibration in the penstock. In this the superposition of impulses may be due to the dimensions and shape of the scroll case and to reflected pressure waves.

There is a distinction to be made in the effects that these impulses produce on the penstock. They may cause only a vibratory increase in pipe diameter though still maintaining the true circular outline of the pipe, or it may accentuate a deformation of the circular outline of the pipe and make the deformation vibratory—otherwise called a breathing of the penstock. At any one point in the pipe the two effects are combined into one result. Either component of the total effect may be the more evident, depending upon the position in the penstock—that is, either near the power house or near the upstream end of the penstock.

In breathing vibrations, the initial or static deformation of the pipe's cross-sectional outline is primarily due to the difference of the hydraulic pressure at the bottom and at the top of the cross-section of the pipe. During the operation of the turbine the static deformation becomes vibratory. The amplitude of motion depends on the ratio of diameter of the pipe to the pressure head on the center of cross-section. During the process of filling the pipe it flattens and reaches a maximum deformation when the level of entering water just reaches the top of the cross-section. It then decreases as the pipe continues to fill—that is, as the differential pressure from top to bottom of the cross-section becomes a less proportion of the total head on the center. The panting would, therefore, be more evident in a large penstock, especially under low head, than in a small penstock under high head.

In the first effect the expansive vibration of the circular outline may only be a few thousandths of an inch, corresponding to several thousand pounds per square inch increased stress. In the vibratory deformation the stress is caused by the bending action of the plate; that is, the main stress of tension is increased on one side of the plate and decreased on the other side. That is to be distinguished from that of the first case where uniform increased tension occurs throughout the entire perimeter of the section and uniformly across the thickness of the plate. Here again the increase in maximum stress from vibrating deformation may be only a few thousand pounds per square inch.

The writer knows of one case in which the amplitude of the breathing amounts to about $^{1}/_{2}$ in., and which seems to have a frequency bearing a definite relation to the speed of the generating unit and which went through repeated uniform cycles of amplitude.

It is conceivable that, in an installation possessing unfortunate conditions as to relative number of buckets and guide vanes and other dimensional conditions of the scroll case and speed of unit, the alternating stresses in either of these two cases might reach overstressed amounts.

The writer believes that the panting action during the operation of the unit receives its impulse from the same causes involved in the author's problem and that such means as are adopted to prevent or decrease such impulses will be beneficial also in correcting the breathing action of the penstock.

[9] Hydraulic Engineer, United Engineers and Constructors, Inc., Philadelphia, Pa. Mem. A.S.M.E.

BYRON E. WHITE.[10] The author has presented a valuable contribution to the literature of hydraulic engineering in clarifying and calling attention to the important subject of vibrations in penstocks. It is fortunate that serious difficulties arise in but few installations. Where such does occur, however, the researches described in the paper will be of great value.

Referring to Mr. Jessop's discussion, in which he calls attention to the massiveness of the usual power-house foundation, in which the turbine scroll cases are solidly encased in concrete as a means of damping out and preventing serious vibrations, the writer wishes to raise a question.

It seems to be customary to employ masses of concrete, sometimes running into many hundreds of cubic yards, in power-house foundations. There are many situations where this is entirely logical, particularly where bedrock is excavated very close to minimum clearances from the necessary water passages, etc., and but little excess concrete is needed to completely fill the voids. On the other hand, there are many situations, particularly in the case of soft ground conditions, where any reduction in mass and weight would reduce the cost of the foundation, particularly where piling is necessary.

In these latter cases, the writer would like to raise the question as to whether it would not be possible to employ very light structures, perhaps even closely analogous to the structural steel foundations frequently employed for steam turbines. The answer undoubtedly lies in the possibility of likelihood of the development of serious vibrations. It would no doubt be rather hazardous to attempt to apply this experimentally in a large installation, since the cost of remedying the conditions, should it prove bad, would be expensive both in construction cost and in the output lost during the down time of the unit, while the work was being done. If there are any cases where this method of constructing a foundation has been either successfully or unsuccessfully tried out, the power industry would be greatly benefited by having a complete recital of the facts made available.

AUTHOR'S CLOSURE

The objection has been made by Messrs. Wilkins and Moody that the method of solving the problem by properly choosing the number of vanes in the runner is not satisfactory. It is said that a more fundamental manner of attacking the problem would be to redesign the shape of the blades so as to eliminate all nonuniformity in pressure. I agree with this completely. Only it must be remembered that the design of a turbine to fit these requirements seems not possible yet with the present state of our knowledge, and a cure in the direction suggested entails hydrodynamical researches of a high order, which take a long time. The solution offered in this paper is a temporary one; as long as perfect turbines cannot be designed, the procedure proposed in the paper will obviate difficulties due to vibration in the penstock. That the perfect turbine in which no pressure variations exist will also have good efficiency is quite probable.

Mr. Moody asks whether it was found that turbines with bad penstock vibration showed at the same time large cavitation. No sufficient data to answer this satisfactorily are known to me, but it might be mentioned that the runner of turbine No. 1 (Table 1) after three months of operation had no signs of cavitation, while the runners of turbines No. 3 and 4 were regularly destroyed by cavitation in about two years.

This would indicate no relation as Mr. Moody suspects, but it is emphasized again that drawing a conclusion from two casual observations would be premature.

In the same light we have to see the case cited by Mr. McCormick in which an installation acted contrary to the theory given here. Apparently no measurements of the vibration were made, and the conclusions were drawn by comparing the actual state of vibration with one which had existed several days or weeks before. Such comparisons depend to a great extent on psychological factors. It is possible that cases will be found contrary to the theory, but I cannot accept Mr. McCormick's statement as a refutation of it. The records taken on the eight installations stated in Table 1, as well as all records published in Mr. Wilkins' article, are in agreement with the theory.

Mr. Moody's objection against the validity of Equation [3] may be true. The equation is meant to be a rough approximation, and the four last cases in Table 1, having heads of about 200 ft., are in fairly good agreement with it. In general, for any individual case it will be better to refer to the more general Equation [1] of the paper.

Mr. Karpov has given a valuable extension to the theory by making a very reasonable assumption about the damping. The influence of the damping in this case is to level down the sharp points of the theory, and thus has the same effect as damping has in other branches of engineering—for instance, in electric circuits.

Interesting remarks have been made by Messrs. White, McCormick, and Jessop on the question of the desirability of lighter concrete foundations than are now in use. An indiscriminate application of light foundations is certainly not commendable, but on the other hand it seems strange that heavy foundations should be necessary in order to insure satisfactory operation.

It seems logical that in the future the foundations of all rotating machinery, including hydraulic turbines, will be made lighter as the art of eliminating vibration advances.
